ADDRESSES AND ORIGINAL ARTICLES

THE STUDY OF SYMPTOMS.*

107

BY JOHN A. RYLE, M.D., F.R.C.P. LOND.,
PHYSICIAN TO GUY'S HOSPITAL.

THE clinical appraisement of disease in man is customarily based upon inquiries into personal and family history and environment; the patient's account, both voluntary and elicited, of his own subjective discomforts; an estimate of his physical type and psychological endowments; and a routine examination of his various systems. In cases of doubt or difficulty we may further employ certain instrumental devices such as the electrocardiograph, or invoke the aid of the radiologist, the chemist, or the bacteriologist. Where none can be neglected it would be difficult indeed to say upon which department of such an inquiry we chiefly rely for our opinions. In one case the patient's ancestry or his own previous pathological career may be all important, in another physiognomy, or the physical examination may give the answer to our question. Often a judical analysis of all available information is necessary. In the earlier part of our clinical training it is usual to stress the importance of physical signs, and long hours are properly devoted to perfection in the arts of palpation, percussion, and auscultation. Nevertheless I am persuaded that with the growth of experience pride of place is often given to symptoms—that is to say, to the purely subjective phenomena of disease. Without symptoms patients would not come to us at all. Symptoms are a part of morbid physiology; they express disturbances of function. As a rule, therefore, they precede the development of signs which are but the outward morbid anatomy of the living.

In the first days of practice we are often baffled by the symptoms which our patients describe and sometimes disconcerted when we find so little of an objective nature to support or explain them. As the years go by, however, we begin to understand and to be grateful for symptoms. Again and again we find ourselves making a reasonable diagnosis while we sit and listen to the patient's story or ply him with our questions, before ever his clothes have been removed or a physical sign has been sought. The majority of patients have indeed little to show in the way of physical signs, for these depend upon advanced structural change. But even in serious forms of organic disease in which, sooner or later, definite physical abnormalities become apparent, symptoms may not only be earlier but also more eloquent than signs. They have, therefore, a particular value for the contributions which they make to early diagnosis. And so, on the score of its practical utility alone, I hope you will bear with my attempts to interest you in a subject which might at first seem to be an elementary part of the daily task of all students of medicine.

There is, however, another aspect of symptomatology and that is the attraction which it offers as a study in itself. For many of us the philosophy of medicine, which runs parallel with the art of medicine pursued for humane ends and with a view to "bread and butter," is a perpetual interest. I am sure we should all endeavour to make it so, for the joys of practice are greatly enhanced if we can also gather in our work some of the crumbs of the philosopher or the natural historian.

I shall, therefore, commend to you the study of symptoms for their own sake as well as for the sake of your patients and your professional reputations. I do so the more eagerly because I feel that the subject still suffers neglect in our generation and that it offers a wide field for future research.

I need hardly remind you that there have been many great students of symptoms whose names and the results of whose researches will abide. In our own island Hilton, Ross, Head, and Mackenzie are famous for their inquiries into the problems of pain. I would commend to your reading as an introduction to the whole subject Hilton's "Lectures on Rest and Pain" and Mackenzie's "Symptoms and their Interpretation." Hurst also in his lectures on "The Sensibility of the Alimentary Canal" deals at length with alimentary pain and other disturbances of alimentary sensation and correlates the results of physiological experiment in man with clinical observation. From these writers and many others whose papers are scattered through the journals we may learn something of the methods which have been evolved for studying symptoms.

Methods of Study.

Two important papers appeared last year in the *British Medical Journal*, one by Sir Thomas Lewis entitled Research in Medicine: Its Position and its Needs, and the other by Mr. Wilfred Trotter entitled Observation and Experiment and their use in the Medical Sciences. The first is critical, stimulating, even provocative and makes an appeal on behalf of clinical science as opposed to curative medicine. It suggests that the experimental study of disease in man, as supplementary to the older observational method, must shortly come into its own and appeals for the appointment and endowment of research physicians who shall be relieved of the necessity of practice. The second is an admirable philosophical inquiry into the relative merits and achievements of the observational and the experimental schools. In the biological sciences it is clear that observation and experiment must ever go hand in hand. The great clinical scientists have commonly made u: of both. It is certain that experiment will lscribe fuller part in the future, but observatior Even continue to make its steady contributions t present ledge. It should be our continual concern and the better observers and better experimence than the it is obvious that only a minority eneral sensations means, the aptitude, or the oppy accompany it. for the life of the experimenter. Tharious ways in continue to enter practice in one form or sitive than every one of these must do his best to ected than observer, or in fact a physician—a student of thought nature, for this (as Prof. Gairdner† so aptly induce many years ago) was the original interpretation di- the word. The more correctly he observes and the more carefully he sifts and records his observations the better practitioner will he be, and the more likely is it that he will render useful service to clinical science. There is no subject that he will have better opportunities of studying than the subject of symptomatology, for he will live in the midst of symptoms. It will, I think, be a very long time before symptoms can be studied experimentally

* An address delivered before the Glasgow University Medico-Chirurgical Society on Jan. 22nd.

† The Physician as Naturalist. Glasgow. 1888.

O

on any considerable scale. Very few of them can be accurately reproduced. The majority of them as they occur in nature are transient. We have no practical method at present of measuring or photographing subjective phenomena. They express the behaviour of diseased or disordered tissues, and like the behaviour of plants and animals we are likely to learn more about them by constant and close observation, by careful recording, and by correlation of these observations with objective phenomena and existing physiological knowledge than by any other process of study.

If we pause for a moment to think of such familiar symptoms as pain and dyspnœa we realise at once that, while our intimate knowledge is slight, we can already classify them into several varieties of pain and dyspnœa and that in certain instances a particular variety has a very special significance. When it has a special clinical significance it also has a special physiological significance, and the actual mechanism of the pain or the chemistry of the breathlessness in such case has commonly been proved. In time it should be possible to sift and classify and analyse all the subjective phenomena of disease in the same way, and the meaning of nausea, heartburn, anorexia, the various forms of breathlessness, vertigo, the various headaches, backaches, heartaches and stomach-aches, the referred pains, the dysurias and dysmenorrhœas, the tinglings and numbnesses, the fidgets and the spots in front of the eyes, will then be made more clear to us. It can scarcely be disputed that diagnosis, prognosis, and treatment will greatly benefit thereby.

That our individual studies of symptoms may prove a pleasant task I shall endeavour to show out of my own small experience. At the same time I shall offer more detailed suggestions for the conduct of the observational method in this field.

Nature and Function of Symptoms.

Symptoms, as has been stated, express a disturbance of function. Although they are often caused by organic disease, they do not express the disease but the disturbance of function which the organic change produces. The same symptoms may thus be produced by functional error or structural flaw. While not specific for diseases, symptoms are, nevertheless, specific for functional errors and these errors, for the most part, depend upon an exaggeration, a depression, inhibition of normal reflex phenomena. The ea of great effort in health is physiologically o the dyspnœa of small effort in heart disease. ina of anxiety or tobacco excess or anæmia ame physiological basis as the angina of rosis, although none of its gravity. nal pain as severe as the pain of intestinal obstruction may occur in gastric or intestinal disease. It is by cer and behaviour of the symptom and by ations that we differentiate. Giddiness may to cerebellar disease, to slight organic changes ne labyrinth, or to transient circulatory effects. gain, it is not on the symptom itself so much as its severity, duration, and associations that we base our diagnosis.

The conception of symptoms as the signals of functional disturbance may seem a very elementary one, but it is none the less important. It is as such rather than as the listed characteristics of diseases that we should wish to view them. We should constantly be asking ourselves "*What does this symptom mean?*" not "*What is it a symptom of?*"

The function of symptoms is presumably protective. Dyspnœa demands general rest for a local and general advantage. Pain in an injured limb compels local rest and so permits repair. The pain of angina pectoris demands instant immobility and so spares the heart in jeopardy from anoxæmia and acute muscle failure. The pain of exaggerated hunger tonus in duodenal ulcer calls for food relief with temporary mechanical and chemical rest for the ulcer. The pain and short, shallow respirations of pleurisy and pneumonia limit the expansion of the chest and rest the inflamed pleura and lung. "Pins and needles" in a cramped limb wake us from sleep and compel us to restore circulation and sensation by movement and friction. Often, we must confess, nature seems to overdo the protective stimulus, for pain may be out of all proportion to the size and gravity of the lesion. Thus the pain of a minute anal ulcer is excessively severe and, although the spasm of the sphincter may shut the canal against the passage of fæces, it is in itself a cause of added pain and by causing constipation may even aggravate the trouble. The protective significance of many other symptoms is obscure, but for the most part they are symptoms whose nature remains at present undetermined. In a more remote and less biological sense symptoms in man are protective in that they compel their victim to seek the advice and aid of others.

The remote physical symptoms of anxiety, hypochondria, and other psychic disturbances are of central origin or to be referred to the emotional plane. They may be due to a loss of balance between vagal and sympathetic activity, or they may be called into action as a mask for truth or as a plea for sympathy. It is also an early lesson of practice that the degree of symptoms primarily due to physical causes may be increased by anæmia, general debility, temperamental factors, or psychic states. Such modifications provide one of the most considerable difficulties encountered in the assessment of the subjective phenomena of disease.

Three Symptoms.

I propose to review some elementary observations on three very diverse symptoms, all likely to be encountered in general practice or medical consulting practice, all capable of expressing organic change or functional disorder, but all—properly assessed—of the greatest help in distinguishing organic from functional disease.

The first symptom is a type of *abdominal pain originating in the colon.* Sometimes of considerable severity it is one for which operations are frequently but fruitlessly performed. The suggested method of analysis of this pain may stand as an example for the analysis of any other visceral pain, and as one plan of attack in the observational study of subjective phenomena.

The second symptom is *nausea.* It is one which may be evoked in health and which occurs in a variety of physical disorders. The method of considering the common factor or factors in the widely varied conditions in which it occurs is another obvious method of approach to an individual symptom.

The third symptom is one of the strangest but apparently one of the most real and vivid of all subjective phenomena. It is the *sense of dying*, the *feeling of impending dissolution*, or *angor animi*, which in the literature is most frequently associated with angina pectoris but which also occurs in several other conditions, as I shall show, and most frequently in the absence of serious structural disease. This symptom being, like nausea, less precise and definable than pain requires other measures of analysis.

COLONIC PAIN.

The particular type of abdominal pain on which these observations are based occurs as a rule in the absence of any demonstrable organic change and is the expression of tonic over-activity or sustained spasticity in the colonic musculature. It is frequently troublesome and persistent, sometimes very severe, and quite commonly leads to appendicectomy or exploratory operations. Here is an account of a case:

A man, aged 30, of spare habit and nervous temperament first began to experience abdominal pains at the time of his final examinations in medicine. After a period of freedom they recurred when he sat for his final Fellowship. They were referred to the right side of the abdomen. Later he experienced them in the upper abdomen and occasionally he had pain in both iliac fossæ. In the past he had suffered from asthma and migraine. When he first consulted me he had been examined with X rays on no less than six occasions, and had been diagnosed as having both a hypertonic and a hypotonic stomach and as a case of "nerves." Fatigue and worry were the chief aggravating factors. On one occasion he thought he had appendicitis, but then discovered that what he took for rigidity was a hardened cæcum or ascending colon. I found a cord-like descending colon, and on another occasion an easily palpable and contracted ascending colon. With reassurance and modifications in his mode of life his health improved greatly. In his attacks he found that belladonna gave him great relief.

The condition has been variously described as spastic colon, spasmodic constipation, and tonic hardening of the colon. It is a visceral neurosis akin to asthma. Its ætiological and clinical characters I have discussed fully elsewhere.[1,2] Anxious to investigate the nature of the disorder and the cause of the pain, I analysed my notes of 50 cases and applied to the pain itself certain tests or queries which have been helpful to me in the study of other pains. These tests or queries are in the form of ten questions relating to: (1) the character of the pain; (2) its degree or severity; (3) its situation; (4) its localisation or extent of diffusion; (5) its paths of reference; (6) its duration; (7) its frequency; (8) its special times of occurrence; and (9) and (10) its aggravating and relieving factors. These are finally correlated with associated symptoms and objective phenomena. The purpose of these questions is simply to make our knowledge of the pain more precise. Too often we are content with the patient's statement that he has a "pain in his belly." As anatomists, physiologists, and psychologists we should desire to know much more than that, and even if we are not dealing with measurable things we should, whenever time and opportunity permit, evolve methods of improving our standards of clinical accuracy.

The answers to these questions in the case of spastic colon are as follows:—

(1) The *character* of the pain is a "dull, steady ache," sometimes gnawing and never "griping" as in the peristaltic pain of purgation or obstruction.

(2) Usually "bearable" it is occasionally so severe as to suggest one of the major "colics."

(3) Its *situation* is in the course of the ascending, the descending, or transverse portions of the colon, in this order of frequency. It may occur in one or more of these situations simultaneously. There may also be rectal pain.

(4) and (5) The *localisation* corresponds accurately with the true surface marking or radiologically observed course of the colon. Sometimes it is more diffuse. Referred pain and tenderness in the somatic planes are rare.

(6) and (7) The *duration* of the pain may be for an hour, hours, or even days. The frequency is very variable and depends largely on personal and environmental factors.

(8) A special *time of occurrence* is two or three hours after food, and of [illegible] during the night when, with warmth and physical and mental relaxation, the pain usually departs.

(9) *Aggravating factors* include cold, fatigue, worry, constipation, purgatives, jolting, exercise, and tobacco.

(10) *Relieving factors* include warmth, holidays, belladonna, and large warm enemata.

Associated symptoms include constipation frequently and diarrhœa less frequently; dysmenorrhœa; urinary frequency; and "dead fingers" in cold weather. The chief objective finding is a readily palpable and firmly contracted colon due to tonic rigidity, shortening and straightening of the affected portion. The sigmoidoscope may show a sustained spasm synchronous with pain. An X ray examination may reveal thread-like narrowing of the bowel lumen, straightening of the affected loop, and disappearance of natural haustrations.

From these and other observations it seems only reasonable to conclude that the pain itself is due to a sustained tonic contraction of the bowel, and that this depends upon an inherent irritability occurring in association with certain physical and temperamental types.

What are the practical and the philosophical advantages of such an inquiry? In practice it enables us with greater confidence and I believe a diminishing margin of error to differentiate an important visceral neurosis from appendicular disease, duodenal ulcer, diverticulitis, carcinoma coli, renal and biliary colic, ovarian and tubal disease, and hypochondria. All of these at times have been alternative diagnoses in the minds of myself or of colleagues who have referred cases of this kind to me.

The philosophical value comes from the application of a definite method to a simple clinical inquiry and from the small increments of knowledge gained thereby. To the physiologist or the physicist the procedure may seem clumsy and lacking in anything savouring of exactitude, dealing as it does with processes which cannot be measured. Nevertheless their precise experimental methods would find no application at the present time in the solution o such a problem. To the field naturalist—and t physician is the field naturalist of medicine— procedure might appear as a reasonable and ap priate attempt to improve the accuracy of observational method.

NAUSEA.

With a symptom such as nausea we are in gr difficulty for, although we understand quite clear what we mean by nausea, we can scarcely describe it in the way that we can describe a pain. Even its localisation is a difficult matter and at present we must accept that it is felt in the pharynx and the epigastrium, sometimes more in one place than the other, sometimes in both together. General sensations of malaise and faintness commonly accompany it. The symptom can be engendered in various ways in healthy people. Some are more sensitive than others and women are more readily afflicted than men. A revolting sight or smell or even the thought or recollection of something unpleasant may induce it, and it here provides a good example of the conditioned reflex. The ingestion of greasy or fatty dishes, of paraffin or castor oil, or the smell of frying—all these particularly in hot weather, when the appetite sense is dulled—are familiar provocatives of nausea. Of foodstuffs it is particularly noteworthy that fats and oils are the most culpable, crisp and savoury foods the least. It appears more easily after repletion. The thing which engender appetite combat it; those which destroy appetite encourage it. Anorexia and nausea are very close allies. Now certain emotions, oils and fats—as can be shown experimentally—

TRANSPLANTATION OF A TERATOMATOUS OVARIAN TUMOUR IN THE FOWL.

PRODUCTION OF A SEX HORMONE BY THE CELLS OF THE TRANSPLANTS.

BY S. L. BAKER, M.R.C.S. ENG., D.P.H.,
CHIEF ASSISTANT IN THE BLAND-SUTTON INSTITUTE OF PATHOLOGY, MIDDLESEX HOSPITAL.

BY the discovery of the filtrable sarcomas of the owl Peyton Rous provided a working basis for the experimental investigation of the virus theory of cancer. In spite of much subsequent work, however, the precise relationship between these fowl tumours and mammalian cancer remains an open question. An important point on which information is lacking is the behaviour of the *carcinomas* of the fowl in respect of filtrability. There has been no material on which to investigate this matter, since up to the present a strain of transplantable fowl carcinoma has never been established. The difficulties of establishing such a tumour strain arise in the first place from the fact that carcinomas in the fowl commonly originate in the ovary or other internal organ and are not diagnosed until the bird is moribund or dead; except by a fortunate chance, therefore, it is impossible to obtain fresh material for transplantation. Epidermal carcinomas occur in the fowl, and Peyton Rous attempted to transplant such tumours arising in the scaly part of the leg; in this case, as with most superficial tumours, unavoidable sepsis was the main cause of failure.

I have had the good fortune to secure a perfect fresh, non-infected ovarian tumour in a fowl; has been successfully engrafted into several birds the first generation of transplants and offers a prosp of establishing the tumour strain.

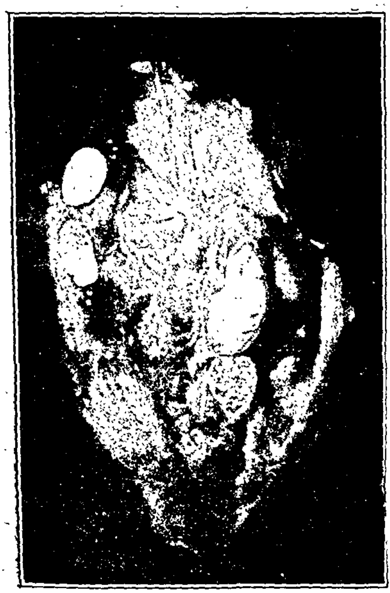
Since this tumour is of interest not only on acco of its histological structure but also by reason of fact that it produces an internal secretion of nature of a sex hormone, I have thought it wo while to give a preliminary account of it.

Description of Tumour.

The tumour occurred in a white leghorn pull The bird was sent to me on account of a hæmorrh spot on the back; when received it appeared in go condition.* I kept it under observation for a f weeks and it still maintained a healthy appeara with a bright red comb as if it were laying; no were produced, however.

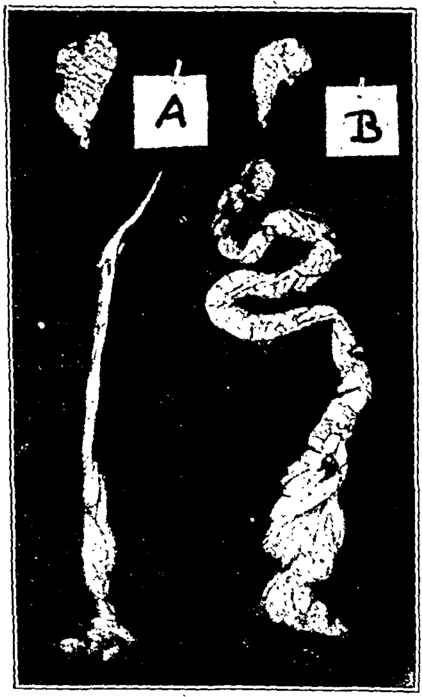
It died suddenly one morning a little time af being removed from its pen for inspection. A p mortem examination made shortly afterwards show that death was due to intraperitoneal hæmorrh associated with a large abdominal tumour; this a rather soft brain-like mass filling the periton cavity and displacing the intestines upwards towards the right. The growth had a smooth crea white surface covered by a network of disten veins; it was composed of several rounded lobu and was attached to the ovarian region by a slen

FIG. 1.



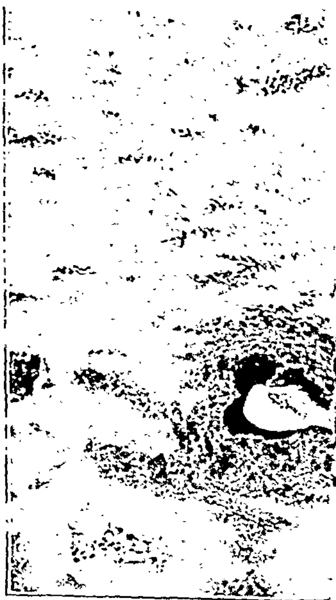
Tumour transplants in bird No. 1. Right side of the breast with the superficial pectoral muscle turned aside. The cut surface of four ovoid tumours are seen. (About four-fifths natural size.)

FIG. 2.



The oviducts and ovaries of a normal control bird (A) and of the fowl bearing the grafts shown in Fig. 1 (B). The control bird was the larger and shows a larger ovary; it has an immature oviduct, corresponding to its age and degree of ovarian development. The tumour-bearing fowl shows a precocious development of the oviduct which is markedly hypertrophied and has assumed the convoluted form. (About four-fifths natural size.)

FIG. 4.



Low power view of a section of one the transplant tumours in f No. 2. Tubules lined by colum cells are seen in the lower part of picture; the upper portion sh the type of tissue which formed main mass of the original and of transplanted tumours. The irre lar patches and strands of c lipoid-containing cells form main feature of this tissue.

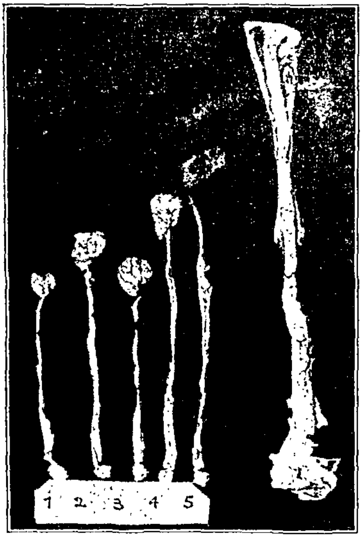
---

* I am much indebted to Mr. R. H. Cory, poultry bree for supplying me with this other tumour-bearing fowls; his coöperation the fresh material required for this work not have been obtained.

pedicle carrying its blood-supply. Some half dozen rounded tumours of the same colour and consistence as the main mass and ranging in size from about 0·2 to 1·0 cm. in diameter were found attached by pedicles to the lower pole of the ovary. Scattered over the mesentery and attached to the surfaces of the intestines were a large number of rounded tumour masses ranging in size from about 0·1 to 2·5 cm. in diameter, the majority being 0·2–0·3 cm.

The ovary, which was intact (the various pedunculated tumours being attached only at the lower pole), appeared immature and showed no signs of ctivity, the largest follicle being no bigger than a in's head. In contrast to this immature ovary I vas surprised to find a large, fully developed oviduct imilar to that of a laying hen. The remaining organs howed no signs of abnormality.

FIG. 3.



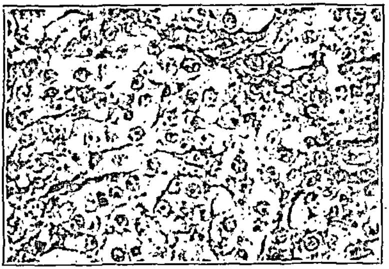
he oviduct and ovary of another tumour-bearing fowl (No. 3) is seen on the right of the picture. The oviduct has been uncoiled and pinned out. For comparison the oviducts and ovaries of five normal birds (1–5) of about the same age. The ovaries of four of these control birds (2–5) are more mature than that of the tumour-bearing fowl; the latter, however, shows a much larger and more mature oviduct. (*Half natural size.*)

TRANSPLANTATION.

(Expt. 182/30 : Oct. 28th, 1930.) A suspension of ragments obtained by mincing portions of the main umour was injected into the pectoral muscles and varian region of a series of fowls. Somewhat over dozen nearly adult fowls, mostly barred rocks, and even white leghorn chicks, 4–6 weeks old, were sed.

Portions of the tumour were also given to Dr. . A. Murray, and were inoculated into a series of owls at the Imperial Cancer Research laboratories t Mill Hill by Dr. L. Foulds. Of the series inoculated y myself only the white leghorn chicks have taken; four of these unfortunately died of intercurrent disease while the tumour grafts were a few millimetres in diameter, one remained negative, in two grafts took well and reached a considerable size. Dr. Foulds obtained takes in several of his fowls, two of which he has kindly handed over to me for examination.

FIG. 5.



A high power view of the clear lipoid-containing cells seen in the previous figure.

These four birds, therefore, form the material for the present preliminary communication; the number is, unfortunately, small but the changes produced are sufficiently uniform and striking to leave little doubt as to their significance.

Three of the tumour-bearing fowls and one negative bird of the same batch were killed 14–16 weeks after inoculation. My fowls which had been kept indoors were only about one-third grown, that from Mill Hill (the same age) was rather more than half grown. The fourth fowl (from Mill Hill) was killed about 19 weeks after inoculation when it was about half grown (weight 900 g.).

Fig. 1 represents the right side of the breast of one of my birds (No. 1) with the superficial pectoral muscle turned aside; it shows four ovoid tumour masses, the largest of which measured about 2 cm. in longest diameter. These tumours were of fairly soft consistence, and showed for the most part a uniform cream-colour surface; in places, however, hæmorrhagic mottling and small cystic spaces could be seen.

My other fowl (No. 2) showed three similar tumours and several smaller nodules. The first fowl from Mill Hill (No. 3) had a considerably larger soft cystic and papillary mass filling the greater part of the right side of the breast; it was yellower in colour than were the tumours in the other birds. The second Mill Hill bird (No. 4) had a rounded tumour measuring about 5 × 6 cm., yellowish-white in colour. There were no secondary deposits in any of the fowls and the peritoneal inoculations had only resulted in a few nodules a millimetre or so in diameter in the first three birds; in the last bird there was a nodule about 1·5 cm. in diameter. On removing the intestines, however, a striking enlargement of the oviduct was at once apparent in all four tumour-bearing birds.

Under normal conditions the immature oviduct is seen to be a thin-walled straight duct extending from the lower pole of the ovary to the cloacal region. It is a flattened strand of tissue with a slit-like lumen; the lower end is imperforate and remains so until full development is reached. Not until there is considerable development of the ovary with the formation of numerous enlarged pedunculated oöcysts does the oviduct show much increase in size. With the continued development of the ovary, however, the oviduct increases in thickness and in length, forming a convoluted tube rounded in cross section.

In Fig. 2 is seen the appearance of the oviducts of a normal control (A) and of a tumour-bearing fowl (B). The control bird was from the same batch as the tumour-bearing chicken, but was somewhat larger; it had been inoculated with transplant material but failed to take. It can be seen that, while the ovary of the tumour-bearing bird (B) is smaller than that of the control, its oviduct has markedly hypertrophied and has assumed the convoluted form. Another feature of the hypertrophied oviduct (which cannot be seen on the figure) is the development of an opening into the cloaca; this is lacking in the control specimen, and indeed in much older fowls with well-developed ovaries and oviducts which have developed to a considerable degree.†

In Fig. 3 is shown the oviduct of bird No. 3, as compared with a series from normal fowls (1–5) of about the same age or somewhat older. In this case the enlarged oviduct has been uncoiled and pinned out straight, and the ovary has been placed beside it. The poor development of the ovary again contrasts with the great hypertrophy of the oviduct.

The condition found in birds No. 2 and No. 4 was similar to that in the two described above.

HISTOLOGICAL CHARACTERS.

Examination of paraffin section of the original tumour and of the transplants shows that the main bulk of the growth is composed of polygonal or ovoid cells. The cell nucleus is rounded and usually contains a prominent nucleolus. Two types of cell can be easily distinguished—one with slightly acidophile, non-granular cytoplasm, the other, rather larger, with clear vacuolated cytoplasm. In addition to this main cellular mass are found sparsely scattered islands containing columnar-celled tubules and small cysts, and also masses and strands of keratinising squamous cell epithelium. These epithelial structures have been found in some of the mesenteric nodules of the original tumour and in two of the transplant nodules in bird No. 2. Sections stained for fat show that the cells with clear cytoplasm are loaded with fatty material which when viewed with polarised light is seen to contain many doubly refractile crystals.

Fig. 4 shows a low power view of a section of one of the transplant tumours in bird No. 2. Tubules lined by columnar cells are seen in the lower part of the field. The upper half of the picture shows the type of tissue which forms the main mass of the tumours; the irregular patches and strands of clear lipoid-containing cells constitute the most obvious feature of this tissue. Fig. 5 shows a high power view of these clear cells. Here the general appearance is not unlike that of the cortex of the suprarenal; the arrangement of the cells is, however, much more irregular.

Discussion.

The histological features of this tumour indicate that it is of the nature of a *teratoma*; the glandular and epithelial elements are, however, scanty and make up a very small proportion of the total bulk of the growth. There is no doubt that the polygonal cells (either the fatty or the non-fatty or both types) are the elements responsible for the production of the hormone. This is shown by the fact that epithelial and glandular elements did not occur in the transplants in birds 1, 3, and 4. There can be little doubt that the fat-containing cells correspond to the "clear cells" which are found in small groups in the theca interna of the follicles of the normal fowl ovary. I have examined frozen sections of normal fowl ovaries and found that these "clear cells" in the theca interna contain in addition to fat doubly refractile crystals similar to those in the tumour cells. These cells were considered by Pearl and Boring (1918) to be homologous with the lutein cells of mammals; this view has, however, not received general acceptance. (Goodale, 1919; Nonidez, 1920.) Goodale considered that they very possibly represented the interstitial cell of the mammalian ovary. As it is now well established that the function of the corpus luteum is to furnish a hormone which produces progestational changes in the endometrium, there seems no reason to expect a homologous structure in birds. A more reasonable supposition would be that the hormone-producing cells of the fowl's ovary represent an original type from which both the œstrin-producing and the lutein cells of the mammal have evolved; however, no definite evidence on this question is at present available.

The non-fatty cells of the tumour are less sharply defined; they appear, however, to grade imperceptibly into the fatty type; there seems little doubt that these cells, like the fatty cells, represent the theca interna of the follicles. It is possible that the cells of the stratum granulosum also are represented.

As regards the nature of the hormone produced by this growth, the general hypertrophy of both the musculature and the mucosa of the oviduct with the canalisation of the genital orifice appears to correspond fairly well to the effect of œstrin upon immature rats or mice; whether the active agent in birds is identical with mammalian œstrin is, however, a matter for further investigation.

This growth has taken comparatively well in the first transplant generation and a considerable number of young fowls have been inoculated from these transplants; it is hoped, therefore, that it will be possible to establish a permanent tumour strain.

SUMMARY.

A teratomatous tumour of the fowl's ovary has been successfully transplanted to the first generation of hosts. The predominating cells in the original tumour and in the transplants resembled those in the theca interna of the ovarian follicles, lipoid-containing cells being a prominent feature. In addition, there were sparsely scattered groups of columnar-celled tubules and keratinising epithelial masses. The original tumour-bearing fowl showed a fully developed oviduct but an undeveloped immature ovary. Young birds bearing tumour transplants showed a precocious development of the oviduct, the cloacal orifice of which became perforate. The ovaries of these birds remained immature.

† According to Glasser, quoted by Lillie, the oviduct does not become perforate until *after* the age of 6 months. I have specimens from several barred rocks 7–8 months old (weight 1800–2000 g.); the ovaries of some contain small yolks, 0·6 cm. in diameter; in none is the cloacal orifice of the oviduct perforate.

INDUCTION OF ABORTION.

BY MARGARET SALMOND, M.D. LOND.,

LATE SENIOR ASSISTANT, OBSTETRIC AND GYNÆCOLOGICAL UNIT,
ROYAL FREE HOSPITAL, LONDON.

THE problem of induction of abortion is always productive of interesting discussion and it may be of value to record all the cases on which this operation has been performed in the obstetric and gynæcological unit of the Royal Free Hospital from 1921 to 1929.

Reasons for Induction.

In all, 50 cases were induced out of a total of 6617 deliveries in the in-patient department during a period of eight years—a percentage of 0·75. There were no deaths in the series. Of these 50 patients, 18 were induced for tuberculosis of the lungs, 11 for cardiac disease, 9 for kidney lesions, 4 for diseases of the nervous system, 3 for carneous mole, and 5 for various lesions: cardiac lesion and acute hydramnios (1), arsenical poisoning and syphilis (1), cardiac lesion and pulmonary tuberculosis (1), following operation for fibrosarcoma of abdominal wall (1), acute dyspnœa ? cause (1).

Tuberculosis.—The reasons for performing induction of abortion for tuberculous disease of the lungs appear to fall into three groups:—

(*a*) Induction early in pregnancy for early active tuberculosis which would inevitably be rendered more severe by pregnancy and the puerperium. Induction is performed so that the patient may at once undergo suitable treatment. *Six cases.*

(*b*) Induction for comparatively advanced tuberculosis which would be rendered worse by pregnancy or the puerperium but, though severe, presents some hope of improvement or cure if suitable treatment can be instituted without delay and unhampered by pregnancy. *Nine cases.*

(*c*) Induction in extremely advanced cases when there is little hope of cure of the patient or even of recovery but when the patient desires intensely that the operation should be performed. *Three cases.*

Induction in tuberculosis is only performed after consultation with a specialist in diseases of the lung. Coöperation between hospitals for diseases of the chest, sanatoria, and maternity hospitals should be encouraged to the greatest extent possible. Most of the cases of tuberculosis are sent to the obstetric unit by special hospitals for the purpose of induction, and it is only after careful consideration that the operation is performed.

Cardiac disease.—Eleven cases were induced, for the following lesions: 1. Mitral stenosis with failure of compensation (4). 2. Mitral stenosis with auricular fibrillation and heart-block (1). 3. Mitral stenosis and regurgitation with failure of compensation (2). 4. Double mitral and double aortic lesions with failure of compensation (1). 5. Complete heart-block (1). 6. Myocardial disease with high blood pressure (1). 7. Congenital pulmonary stenosis (1).

The majority were mitral stenoses with failure of compensation early in pregnancy. These were all patients who had had a number of children and in whom the cardiac lesion had become progressively worse with each pregnancy. In a few cases of cardiac failure of sudden onset which does not respond to treatment, induction of abortion may be necessary, but in these multiparæ it would probably have been better to perform Cæsarean section and sterilisation during an earlier pregnancy. This, however, may not always be possible, as the wishes of the parents have to be taken into account, and sterilisation may be refused.

The onset of auricular fibrillation during early pregnancy is almost always an indication for the induction of abortion, as is the presence of complete heart-block; though in the one case recorded with this lesion the previous pregnancy had been undergone with no symptoms, except during the second stage of labour, which was terminated by forceps owing to the onset of cyanosis. Severe lesions of the myocardium may be an indication for induction, if failure is apparent in the early stages of pregnancy. Congenital lesions rarely present any indication for induction and the case recorded, in view of recent work on cardiac cases and of the history of the case, was probably induced unnecessarily.

Again, no operation is undertaken without consultation with the cardiologist attached to the department. The obstetric unit has had for a number of years a special antenatal cardiac clinic, and all cases with any suspicion of cardiac lesions are referred to the clinic and there undergo thorough investigation.

Renal lesions.—Nine cases were induced for lesions of the kidneys: 1. Chronic nephritis (4). 2. Acute exacerbation of chronic nephritis (1). 3. Acute nephritis (1). 4. Acute pyelitis (3).

By far the most important group in this series is the first. In view of the serious effects of pregnancy on chronic kidney lesions, it is wise not to postpone termination of the pregnancy for too long, as the lesion is in all cases rendered worse by the pregnancy and puerperium. This applies also to groups 2 and 3. Consultation with a physician and careful and frequent biochemical examinations should be performed before and after induction.

Pyelitis during pregnancy is rarely so severe as to necessitate the induction of abortion. It usually yields quickly to treatment by large doses of alkalis. Induction on the one case in this series was performed because the patient had previously had a nephrectomy.

Diseases of the nervous system.—4 cases: 1. Parkinsonian syndrome following encephalitis lethargica. 2. Tabes dorsalis. 3. Disseminated sclerosis. 4. Epilepsy.

Few diseases of the nervous system necessitate the induction of abortion. Epilepsy, unless very severe, is not usually an indication. The cases of tabes dorsalis and disseminated sclerosis had great difficulty in walking and the patient with the parkinsonian syndrome was in very poor condition and unable to get about at all. In all these cases the lesions were definitely rendered worse by the pregnancy.

Obstetrical lesions.—5 cases: 1. Carneous mole (3). 2. Acute hydramnios with collapse of right lung and mitral stenosis (1). 3. Acute hydramnios (1).

Miscellaneous medical and surgical lesions.—4 cases: 1. Pulmonary and laryngeal tuberculosis and mitral stenosis with heart failure. 2. Arsenical poisoning and syphilis. 3. Following removal of fibrosarcoma of right rectus abdominis muscle. 4. Acute dyspnœa of unknown origin.

Carneous moles are occasionally expelled spontaneously but often require interference. Induction should only be performed after careful observation to make certain that the pregnancy is not continuing. Acute hydramnios is a comparatively rare condition but the treatment and method of induction is simple.

The incidence of cardiac disease and pulmonary tuberculosis in the same patient is uncommon, as is arsenical poisoning following on treatment for syphilis. The patient from whom a fibrosarcoma had been removed would, if the pregnancy had been allowed to continue, have been liable to a very severe strain on the abdominal scar and her abdominal musculature would have been very weak. In the last case in the series, which occurred some years ago, the notes are too scanty to allow of an accurate diagnosis.

Detailed descriptions of all the cases in the series have been omitted for lack of space.

Methods Used.

The methods used were as follows: 1. Drugs alone. 2. Drugs combined with other methods. 3. Rupture of membranes with or without dilatation of the cervix. 4. Dilatation of the cervix and insertion of small bag. 5. Stomach-tube. 6. Bougies. 7. Version and pulling down a leg after dilatation of the cervix. 8. Dilatation of the cervix and clearing out the contents of the uterus with finger and ovum forceps. 9. Packing the vagina alone. 10. Insertion of rubber catheter into uterus and packing the vagina. 11. Dilatation of the cervix and insertion of gauze wick soaked in glycerin into the uterus and packing the vagina. 12. Dilatation of the cervix and insertion of laminaria tents with or without packing the vagina. 13. Insertion of catheter (self-retaining) filled with glycerin into the uterus, combined with laminaria tents and packing the vagina.

1. *Drugs alone.*—Drug induction by castor oil and hot baths, followed by quinine or injections of oxytocin, appears to have little value in the induction of abortion. From experience we have found that the uterus is only sensitive to the action of these drugs when approaching term. Drugs alone were used in four cases and failed in all (8 per cent. of cases—100 per cent. failures).

2. *Drugs in combination with other methods* were sometimes given and appeared to improve the strength and frequency of uterine contractions once these had been initiated.

3. *Rupture of membranes* with or without dilatation of the cervix was used in two cases, one in each category (4 per cent.), with success in both: in the first 48 hours later, in the second five hours later. This method is eminently suitable and successful for cases of acute hydramnios.

4 (*a*). *Dilatation of cervix, rupture of membranes, and insertion of hydrostatic bag* was used in one case (2 per cent.) with success 48 hours later. This method is to be condemned in that the insertion of a hydrostatic bag after rupture of the membranes involves a grave risk of sepsis.

4 (*b*). *Dilatation of cervix and insertion of small hydrostatic bag* was the method in eight cases (16 per cent.) with success after three days in two cases (25 per cent.) and failure in six cases (75 per cent.). This method is not to be recommended. It is as a rule slow and unreliable. It also almost certainly involves dilating the cervix with Hegar's dilators to a fairly high number (about 20). This procedure necessitates an anæsthetic, which in many cases is inadvisable.

5. *Insertion of a stomach-tube*, combined with packing the vagina, was used in seven cases (14 per cent.) with success in six cases, on an average 34·8 hours later (85·7 per cent.), and failure in one case (14·3 per cent.). This method has good points but is only suitable for inductions of abortion from the twentieth to twenty-seventh week, as the stomach-tube is usually too large to be used before that time. Success depends upon getting as much as possible of the tube into the uterus between the membranes and uterine wall. An anæsthetic is rarely needed except for very nervous primiparæ. The time of onset of pains is variable; sometimes rapid, sometimes slow. Labour is hastened by dipping the tube in glycerin before inserting it into the uterus and by packing the vagina with gauze soaked in glycerin and flavine. The method is to be preferred in the induction of labour.

6. *Bougies*, combined with packing the vagina, were used in one case (2 per cent.) with success three days later. The remarks about induction with the stomach-tube apply to this method but there is the disadvantage that the danger of sepsis is probably greater, as several bougies are usually inserted, and also there is more danger of separating the placenta.

7. *Version and pulling down a leg* after dilatation of the cervix and rupture of the membranes was the method in eight cases (16 per cent.) and had no failures. Success was achieved on an average 27·7 hours later. This method is successful and often rapid, but again necessitates previous dilatation of the cervix and intra-uterine manipulation with consequent danger of sepsis, and requires anæsthesia.

8. *Dilatation of cervix and clearing out uterus* under anæsthesia by the rapid method was used in seven cases (14 per cent.) with success in five cases (71·4 per cent.). In two of these cases severe hæmorrhage occurred. One was followed by sepsis, necessitating a hysterectomy later. The uterus was incompletely emptied in two cases, the rest of the products of conception being passed some days later. This was a failure in technique. This method has the advantage of being rapid, but the grave disadvantage of being associated frequently with severe hæmorrhage and shock. It necessitates an anæsthetic.

9. *Packing the vagina and cervix only* was tried in two cases (4 per cent.) but both were failures. This method is useless alone.

10. *Insertion of catheter into uterus and packing the vagina* was used in three cases (6 per cent.) with two successes (66·6 per cent.). This method is very uncertain, as the introduction of a small catheter is rarely a sufficient stimulus to initiate uterine contractions.

11. *Dilatation of cervix and insertion of gauze wick*, soaked in glycerin into uterus, and packing the vagina, was the method in two cases (4 per cent.) and both were successes. In this method, again, the gauze wick inserted between the membranes and uterine wall, even when soaked in glycerin, appears to be an insufficient stimulus to initiate uterine contractions rapidly and the method may have to be repeated.

12. *Insertion of laminaria tents* with or without catheter and previous dilatation of cervix and packing the vagina was done in 16 cases (32 per cent.) with success in ten cases (62·5 per cent.), and failure in six cases (37·5 per cent.). Laminaria tents alone are rather uncertain. Success is more often ensured when several tents and not one alone are inserted. It is possible that the chance of success is increased when the vagina is packed tightly with gauze soaked in glycerin. The advantage of tents is that an anæsthetic is rarely necessary.

A METHOD OF CHOICE.

13. *Insertion between the uterine wall and membranes of a self-retaining catheter* filled with glycerin, injection of 10 c.cm. of sterile glycerin into the uterus, insertion of two or three laminaria tents into the cervix, and packing the vagina with gauze soaked in glycerin and flavine. This was the method in eight cases (16 per cent.) with success in all (in one case the first induction failed, but the second succeeded three days later). The average length of time elapsing before abortion took place was 26 hours.

This method has been the most successful and has been in use in the obstetric unit for the last two years. As far as can be seen from a very small number of cases, it promises to be a valuable addition to the methods already in use and merits further trial.

The cases reported were about 16 weeks pregnant and it is for this type of case that it has been found most useful. No anæsthetic is needed if the patient is a multipara, and the method is practically painless. The patient is placed in the lithotomy position and the usual aseptic precautions are taken. The cervix is grasped gently with a pair of sponge forceps and a No. 7 self-retaining catheter, filled with sterile glycerin, is passed into the uterus between the membranes and the uterine wall as far as possible. About 10 c.cm. of sterile glycerin is then injected into the uterus by means of a record syringe. Three or four laminaria tents are then inserted through the cervix and the vagina is packed with gauze soaked in glycerin and flavine. The pack is removed in 12 hours and the catheter, if necessary, left for 72 hours. It is rarely necessary to leave the catheter in as long as this, as abortion usually occurs before 72 hours have elapsed. For success, it is essential that (1) as many tents as possible should be inserted and (2) the tents and catheter should not be removed early. In the successful cases the tents and catheter are expelled with the abortion.

In performing induction of abortion upon patients suffering from cardiac lesions or pulmonary disease it is of value to use a method which is comparatively rapid yet does not cause shock or hæmorrhage, as is often the case when a uterus is cleared out by dilating up the cervix under anæsthesia and removing the ovum with the finger and sponge forceps. It is also of value in some cases to have a method which can be carried out without an anæsthetic.

The method described, as far as can be gathered from the results of a very few cases, appears to fulfil these conditions and merit further trial. No ill-results have followed on the injection of glycerin into the uterus.

Advantages of Induction.

At a recent meeting of the Edinburgh Obstetrical Society, Dr. W. F. T. Haultain[1] reviewed a series of patients on whom abdominal hysterotomy had been performed for the purpose of therapeutic abortion. He regards it as an operation superior to slower methods, especially in primiparæ, "where induced abortion between the third and sixth months is a most painful and tedious business." With this statement I venture to disagree; I find that the last method described in this paper produces admirable results with very little pain or delay and without the necessity for an abdominal operation. The abdominal hysterotomy, however, has an advanatage in the treatment of hydatidiform mole and also in that sterilisation can be performed at the same time.

With advance and improvement in the art of medicine and obstetrics, it is often possible to avoid operative procedures such as the induction of abortion. The early recognition and improved treatment of diseases of the heart has reduced the numbers of cases needing this operation. It is now only performed on selected cases, especially those in whom treatment during the early stages of pregnancy has failed to improve failing compensation. We must hope that in the future the great efforts which are being made towards the prevention of rheumatism will considerably reduce the incidence of rheumatic cardiac lesions. This will undoubtedly have its reflection in the incidence of cardiac lesions during pregnancy and will be a factor in the reduction of maternal mortality. We must hope, too, for some equally striking efforts towards the prevention of tuberculosis of the lungs. Improved antenatal care has helped very largely to reduce the severe toxæmias of pregnancy. Induction of abortion is rarely necessary in these diseases, as toxæmias are more often found during the later months of pregnancy. Again, it is to preventive medicine that we must look for aid in decreasing the number of chronic kidney lesions, some of which follow toxæmia in a previous pregnancy; from this cause arise a number of cases in which it is necessary to induce abortion.

Another problem of great importance that must always be kept in the mind of the obstetrician who undertakes the operation of induction of abortion is the possibility and advisability of future pregnancies. In specially selected cases, for a cogent reason—cases in which a future pregnancy may be contemplated with hope of a successful conclusion—it is a justifiable operation. In many cases—for example, in patients with very severe cardiac lesions who may at a later date again become pregnant, necessitating perhaps another similar operation—the induction of abortion is highly unsatisfactory. If possible, in this type of case, some safe method of preventing further pregnancy is more desirable. The only completely safe method involves sterilisation of the patient by operation, X rays or radium therapy being occasionally unreliable. Sterilisation will not always be accepted by patients. Induction of abortion alone will remain as a method of treatment in a certain number of "undesirable" cases. In this type of case, medical advice with regard to contraceptive methods may be of value after the operation.

The relative merits of (1) induction of abortion alone, (2) induction of abortion followed by some suitable method of sterilisation, (3) Cæsarean section and sterilisation (in those cases where the condition would permit of the continuance of the pregnancy nearly or quite to full term) must be considered seriously in all cases under observation.

I am indebted to the Director of the Unit, Dame Louise McIlroy, for permission to publish these cases.

INTENSIVE SERUM TREATMENT OF CEREBRO-SPINAL FEVER.

BY H. STANLEY BANKS, M.D. GLASG., D.P.H.,
MEDICAL SUPERINTENDENT, ISOLATION HOSPITAL AND SANATORIUM, LEICESTER.

THE clinical potency of antimeningococcal serum in any given case depends upon the amount of anti-endotoxin contained in the serum against the particular type of meningococcus concerned.[1] Probably the best results ever obtained in the treatment of established cerebro-spinal meningitis are those recorded in the first official report on Type I. univalent antimeningococcal serum[2]—viz., 33 recoveries out of 34 Type I. cases treated. This was the remarkable result obtained towards the end of the war period with this highly specific serum in the hands of known, careful, and active clinicians.

Very few of the practitioners who are now called upon to treat cases of cerebro-spinal fever have had personal experience of treatment of the disease with univalent type serum. For this reason, and also because of the difficulty of rapidly determining the type of infecting organism in any given case, there has been no effective demand for univalent serum since the war, and, in consequence, little or none of it has been produced. I had the fortunate experience of treating a few cases with this serum in the years 1919 and 1920. Its highly specific action was seen particularly in the case of a child aged 15 months, in the fourteenth day of the disease with turbid cerebro-spinal fluid containing Type I. meningococci. In this case, the temperature fell to normal by crisis and all clinical signs of the disease disappeared *within 12 hours* of the intrathecal injection of a single dose of 20 c.cm. univalent Type I. serum.[3] It seems, therefore, a matter of great regret that the Departments of State concerned have not seen fit to maintain a supply of this highly potent serum since the war. The serum available on the market to meet the outbreak of 1931 is of the multivalent variety, and according to M. H. Gordon (personal communication, March 7th, 1931) it contains little or no anti-endotoxin against the dangerous Type I. meningococcus.

---

[1] Brit. Med. Jour., 1930, ii., 62.

In general it may be said that the therapeutic potency of the multivalent antimeningococcal serum available in recent years in this country is weak. Reference to the Glasgow outbreak of 1929,[4] with its mortality-rate of 83·6 per cent. among 134 cases, and to the Lanarkshire figures for the ten years 1920–29 (83·1 per cent. among 65 cases[5]), seems to afford tragic confirmation of this statement.

Gordon has pointed out that great improvement in the therapeutic potency of antimeningococcal serum available to the troops took place in the later years of the war, and associates with this fact the 35 per cent. military mortality in 1918 compared with the 60 per cent. mortality in the same year among civilian males aged 20 to 30.[1]

ROUTE OF INJECTION.

If we are compelled to use a weak therapeutic serum it seems obvious that larger doses are indicated than those generally used in the case of a potent serum. The method of serum administration generally recommended in the meningitic stage of cerebro-spinal fever is repeated intrathecal injection of amounts of about 20 to 40 c.cm. after lumbar puncture and evacuation of rather more than this quantity of cerebro-spinal fluid. By intrathecal injection alone it is impossible or inadvisable to give larger doses of serum on account of the dangerous rise of pressure in the cerebro-spinal system which might take place. If larger doses of serum are to be given and to be rapidly absorbed, the routes available are the intramuscular, intravenous, and intraperitoneal. By these routes it is quite practicable to give doses of serum of 100 to 200 c.cm. at a time.

It has, perhaps, been too readily assumed that antimeningococcal serum injected by these routes is inert *in the meningitic stage of the disease*; Worster-Drought and Kennedy in their monograph[6] (p. 404), make the following statement:—

> "In the presence of meningitis, serum injected subcutaneously or intravenously is useless; not only does it undergo an extremely high dilution in the blood stream, but there is considerable doubt if it ever reaches the subarachnoid space at all. Dixon and Halliburton and others have shown that although the lining membrane of the subarachnoid space is permeable to substances passing from the cerebro-spinal fluid to the blood, it appears quite impermeable, excepting in the case of a few drugs—e.g., hexamine, and oxygen in the reverse direction—from blood to cerebro-spinal fluid."

This objection appears, however, to be a purely theoretical one in so far as antitoxin is concerned. The method of injection of large doses of antimeningococcal serum intravenously in the meningitic stage does not appear to have been put to a practical test *on any considerable scale in this country*, although it has been done in the United States Army with marked success in a small series of cases by Carbonell and Cook.[7] It seems, moreover, an unwarrantable assumption that because certain foreign materials do not penetrate from the blood to the cerebro-spinal fluid, therefore antitoxin administered intravenously will have no curative effect against organisms lodged in the meninges and elsewhere.

The practical clinical test, although it may be difficult to evaluate, must be the supreme and final arbiter in such a matter.

Intensive Serum Treatment.

Since 1927, it has been my practice to give large doses of multivalent serum—e.g., an initial dose of 100 to 200 c.cm. intravenously—and to do repeated lumbar punctures at 24 or 48 hour intervals, with or without an initial intrathecal administration of serum. There have been a few exceptions to this rule. In the first case treated with a large dose, improvement seemed to date from the administration of 50 c.cm. *serum intramuscularly and 50 c.cm. intrathecally.* In two cases aged 6 months and 15 months, 100 c.cm. and 110 c.cm. respectively were given *intraperitoneally.* In a few cases, chiefly in young infants, intravenous injection was not found to be practicable. In most cases, however, a single dose of 150 to 200 c.cm. was given intravenously. In some cases a second somewhat similar dose—e.g., 100 c.cm.—was given after about 48 hours, if little improvement in the clinical condition had occurred, or, at a later date, in the event of a recrudescence. In one case the intravenous injection was repeated twice, on the eighth and nineteenth day after the first injection, on account of recrudescences, even though, of course, it was recognised that there was a risk of anaphylaxis. At the third injection an immediate serum rash

TABLE I.

Age-grouping.

Age-group ..	0–1	1–2	2–5	5–15	15–30	Over 55	Total.
Recovered cases ..	2	4	2	5	2	—	15
Fatal cases	2	1	3	2	—	1	9
Total	4	5	5	7	2	1	24

Percentage of cases in unfavourable age-groups—i.e., under 5 years and over 55 years =62·5.

Day of Disease on which Treatment Commenced.

Day of disease	2nd	3rd	4th	5th	6th	7th	8th	10th	11th	12th	14th	21st
Recovered cases ..	—	1	2	3	2	2	1	1	2	—	—	1
Fatal cases ..	1	1	1	1	—	—	—	1	1	1	2	—
Total ..	1	2	3	4	2	2	1	2	3	1	2	1

Fatal Cases.

The following features were associated with the fatal issue in nine cases.

Died within 48 hours of admission (fulminating type)	3
Repeated lumbar puncture unsuccessful or infrequently performed	3
Collapse after intrathecal administration ..	1
Age 5 weeks	1
Age 56 years	1

Fatality-rate: 37·5 per cent.

Complications: one case, paresis of arm and face.

appeared, but no dangerous symptoms. Clinical improvement followed rapidly on this third injection, and complete recovery ultimately took place.

During the period April, 1927, to March, 1931, 29 verified cases came under treatment. Of this number, five cases, aged 9 weeks to 2 years, have been excluded from the series, as it was found impossible to give them intravenous serum. The remaining 24 cases were all treated by the intensive method with the results set out in Table I.

The series is too small for conclusions to be drawn, but in view of the unfavourable age-grouping the mortality may be considered significantly low. A prima facie case for further experiment on the lines of intensive dosage, where the serum available is weakly specific, appears to be made out.

The clinical results in the series have not usually suggested a highly specific phenomenon like that obtained in Type I. meningococcal meningitis with the monotypical serum. As a rule, the temperature fell after two to eight days and a gradual clinical improvement set in after two to three days. It was realised in the later stages of the investigation that daily successful lumbar puncture enhanced the chances of recovery in those who did not respond too well to the initial large dose of serum. Had this fact been fully realised earlier, it is possible that three of the fatal cases might have been saved

ILLUSTRATIVE CASES.

The following cases suggest a specific effect of intensive serum treatment. Case 1 had intravenous and intrathecal serum. Case 2 had one dose of intravenous serum only.

CASE 1.—*Boy aged 11 years. Complained of headache* and malaise on Sept. 10th, 1929. Admitted to Royal Infirmary, Leicester, on the 12th; headache then severe, restless, nucal rigidity marked; Kernig's sign positive; temperature 99·8° F. Cerebro-spinal fluid, under pressure and turbid; smears crowded with polymorphs. Sept. 15th, temp. 101°–103° F.; meningococcus grown on culture from cerebro-spinal fluid. Admitted to Isolation Hospital, Leicester (sixth day of disease) very restless, noisy, headache severe, and head retraction extreme.

Treatment. — 160 c.cm. antimeningococcal serum (Burroughs, Wellcome and Co.) intravenously, 40 c.cm. intrathecally. Sept. 16th, opisthotonos present; child most restless, delirious, and shouting out. Lumbar puncture: 60 c.cm. thick *purulent* fluid removed (deposit of ¼ inch yellow pus on standing 3 c.cm. fluid in test-tube). Sept. 17th, opisthotonos extreme; oscillatory movements of eyeballs, very restless. Lumbar puncture: 27 c.cm. purulent fluid removed; 25 c.cm. serum given intrathecally. Sept. 19th, child quieter; head retraction extreme, but opisthotonos less. Lumbar puncture: 47 c.cm. *faintly turbid* fluid. As child appeared to be improving a second large dose of serum, 150 c.cm., was injected intravenously and 25 c.cm. intrathecally. Sept. 20th, child says he feels much better; quiet; no opisthotonos, but head retraction still present. Sept. 21st, lumbar puncture: 39 c.cm. faintly opalescent fluid. Sept. 23rd, much better; no opisthotonos, no head retraction, no rigidity of limbs; taking food well. Lumbar puncture: 26 c.cm. *clear* fluid. Serum rash present. Sept. 25th, lumbar puncture: 56 c.cm. clear fluid. Oct. 11th, very well; allowed up. Oct. 21st, discharged; walking well; no symptoms.

CASE 2.—*Girl aged 18 years. Complained of headache* and pain in back, Jan. 16th, 1931; delirious on the 17th. Admitted to Isolation Hospital Leicester, on the 19th in semi-comatose condition, very restless, and delirious; nucal rigidity marked; Kernig's sign present. Lumbar puncture: very turbid fluid under pressure, containing numerous pus cells and intracellular diplococci.

Treatment. — 200 c.cm. antimeningococcal serum (Burroughs, Wellcome and Co.) intravenously; serum not given intrathecally. Jan. 20th, rigidity more marked; condition generally about the same; temp., 101·4° F. Jan. 21st, rigidity much less; mentally bright; no further delirium. Lumbar puncture: 28 c.cm. slightly turbid fluid. Jan. 22nd, markedly improved; no rigidity; mentally alert. Jan. 23rd, temperature normal. Jan. 24th, lumbar puncture: 42 c.cm. faintly turbid fluid. Jan. 26th, complains again of headache, sickness, and vomiting; evening temperature 101·4° F. Jan. 27th, temperature normal. Jan. 28th, lumbar puncture: 18 c.cm. slightly turbid fluid; evening temperature, 101·8° F.; appears fairly well; no rigidity. Jan. 31st, slight headache; evening temperature 101·2° F.; lumbar puncture: 35 c.cm. faintly turbid fluid. Feb. 2nd, quite well; no rigidity; temperature normal. Feb. 11th, allowed up. Feb. 23rd, discharged. Walking well; no symptoms.

SERUM REACTIONS.

A peculiar feature is that very rarely has any immediate serum reaction followed intravenous injection of these large doses of serum in this group of cases, with the exception of one case where subsequent injections were given more than ten days after the first. As a rule, patients became quieter after the injection, and colour was, on a few occasions, rather poor for an hour or so. Not a single rigor occurred. It seems amazing how well these large *doses of intravenous serum are tolerated in this* disease as compared, for example, with diphtheria. Serum rashes occurred in every case but gave no trouble.

INJECTION IN INFANTS AND YOUNG CHILDREN.

It is undoubtedly difficult to get a needle into a vein of a restless child under 2 years of age, and to inject about eight syringefuls of serum into the blood stream. Nevertheless, it can usually be done with practice and a correct technique.

Several good needles are essential, with sharp point, short bevel, reinforced mount, rigid shaft about 1¼ in. long and bore 0·8 mm.; at least three 20 c.cm. syringes with peripheral nozzles are required. A vein at the bend of the elbow is tried first, the arm being hyperextended at the elbow and firmly squeezed from above and below towards the elbow in order to distend the vein. If failure is encountered here, the external jugular vein can usually be entered more readily. If this fails, a vein in the arm may be dissected out, but this method is not so simple as it appears. Lastly, if all attempts fail, it is justifiable to give the serum *intraperitoneally* in such a serious disease. Absorption from the peritoneum is very rapid, and this route proved successful in the two cases in which it was tried. Intramuscular injection is not suitable for large amounts of serum, as it is a painful process and absorption is slow.

Summary.

1. It is suggested that when it is impossible to determine the type of infecting meningococcus, and to apply the specific univalent serum, as at present in this country, the available multivalent serum, which is weakly specific, should be injected in large doses of 100 to 200 c.cm., preferably intravenously, and, if that is impossible, intraperitoneally, in addition to the usual treatment.

2. In a small series of cases with unfavourable age-grouping and generally coming under treatment at a fairly late stage the mortality was 37·5 per cent.

3. This mortality compares favourably with that reported in similar series in recent years in this country.

BOILS AND CARBUNCLES AMONG MINERS.

BY S. W. FISHER, M.D. DUB.,
H.M. MEDICAL INSPECTOR OF MINES.

ATTENTION was recently drawn to the occurrence of boils and carbuncles among miners by the noticeable number of men at a certain colliery who were afflicted with them. Inquiries at this mine made evident various factors, any of which might have been the cause of the cases found. Of these factors three were outstanding: (*a*) the temperature at the working face—dry bulb 90° F., wet bulb 80° F.; (*b*) the hardness of the drinking-water; and (*c*) the fact that most of those suffering from boils were men who had been off work for terms up to two years and who were newcomers to the district. In order to determine more exactly which of these factors was the material one, 20 other collieries were visited and information received from 29 more. About 200 men were examined or interviewed.

A TWO-SIDED INVESTIGATION.

The investigation at the various collieries resolved itself into two parts—namely, examination of the men and examination of conditions at the mine. At each mine the following points were noticed: depth (shaft and workings where a marked difference existed), thermometer readings as given by the ordinary wet and dry bulb thermometer, type of coal, state of ventilation, and quality of drinking-water. The depths of the mines visited ranged from 300 to over 1000 yards, and the distances inbye to the working places up to 2½ miles. The highest temperature met with at the face was 93° F. dry bulb and 85° F. wet bulb; the lowest was 53° dry and wet bulb. In mines where the wet bulb temperature was about 75° or over the men worked partially stripped—i.e., shorts and boots—and the occurrence of boils was most noticeable in mines where the temperature at the face reached or passed this figure. I observed, too, that boils occurred more often on men who sweated profusely and whose bodies were covered with a fine wet film of coal dust—as one man put it, "the body is as if covered with boot polish."

On the whole ventilation was good; when it was noticeably otherwise a temporary cause, such as a fall of roof in an airway, or the extraction of water before the making of a new airway, was the explanation. Several Petri dishes containing a culture medium were exposed in the intake and return airways and at the working face in order to test the bacteriological purity of mine air, the exposure in some cases being for 15–20 minutes; in no case was any pathological micro-organism found.

Most types of coal were met with and, apart from the fact that some seams are hot and some coals generate a very fine dust which is more difficult to wash off completely (the men use soda in their baths), I have no reason to think that the composition of coal has any influence. As regards water underground, droppings from the roof sometimes cause smarting and irritation, especially severe when in bed at night. At one colliery a supply of vaseline was kept underground for the men to rub into their skin after working. A sample of such a water contained 186·51 parts per 100,000 sodium chloride.[1] The soaking of the skin through working in wet places lowers its vitality and facilitates the entry of staphylococci. This is well known to be a cause of prepatellar cellulitis (miners' beat knee).

THE FINDINGS.

I considered it of some importance to try to determine the position where the first boil started. In many cases this could be traced to a small scratch or injury; 10 cases started on the knee, and 8 of them might have been diagnosed as miners' knee, which is a compensatable disability. In other cases the original focus was: back (9), elbow and forearm (9), lower third of leg (7), fingers (5), wrists (5, 3 of them in surface workers), toe (1), buttock (3), face (4), axilla (2), shoulder-blade (1, a filler), neck (1), ankle (1), abdomen (1), and thigh (4). It is worth remembering that most men wear a belt, or a substitute, and none wears a collar. In many cases, but by no means in all, there was a likelihood of infection from house mates, the landlord, landlady, or another lodger having had them just before. Cases also followed one another in a given working stall.

At the first colliery to which my attention was drawn, where the complaint assumed its most serious proportions, of 12 men examined, 9 had only recently started work, having been idle for periods ranging from one month to two years, during which time they were living on their unemployment insurance. They became infected after an average of 7½ months at their work (one week to two years). On the other hand, boils were not common among the men of long-standing at the mine, and one is led to the supposition that a lengthy enforced idleness and probably poor nourishment causes lower resistance among the men. Similar observations have been made in the case of miners' beat hand and beat knee.

The hardness of drinking-water has sometimes been blamed for boils. This is a point that is not easy to decide. The water drunk by miners at the colliery where the greatest number of cases occurred was found to have 16° hardness, but a neighbouring mine with a similar water-supply had very few cases. A mine which had never had many cases and which had none at the time of my visit had drinking-water of 40° hardness. Again, at many mines boils occur only in certain stalls, although the drinking-water is the same for all. What may be of importance is the fact that many men in warm mines drink large quantities of water and thus lower the percentage of chloride in the blood fluid.

No mines having pithead baths, with one exception (where boils were very few), were reported as having cases of boils. In my opinion, pithead baths must be a valuable preventive.

As regards treatment, I recommend the use of manganese injections and treatment of the local lesion by painting it with contractile collodion.[2] To the managers of mines where boils occur I suggest that every effort should be made to improve the ventilation, lower the temperature, and minimise wetness. To the men my advice is to apply an antiseptic, preferably tincture of iodine, to the smallest scratch, cut, or boil, as soon as possible, and avoid touching the boil with the fingers, to drink as little water as possible, and preferably water that has a small amount of salt added to it (about 10 g. to the gallon), and whenever available to make full use of pithead baths.

---

[1] Powdered oatmeal in the bath-water may be both a preventive and may help to cure. This is used a great deal for prickly heat in India—a condition which mostly occurs in the rainy season. In the rainy season people in India suffer from boils, usually a large number of small boils. These multiple boils often mean that a "prickly heat" rash has become septic —i.e., has become infected by the staphylococcus. Horses suffer from a type of ulcer, also during the rains. The Indians call it Barsati or Burrsati because it only occurs in the monsoon (Barsat). If a horse get a barsati sore, he will have an annual recurrence and will be free when the rains stop and the atmosphere becomes cooler and more dry. In the hot weather (up to 115° F.) the skin is dry; in the rains the temperature is between 80° and 90°F. and the skin is damp, if not actually streaming.

[2] See THE LANCET, 1930, i., 946.

CONCLUSION.

In conclusion, I am of opinion that as far as mines are concerned, boils do not present a serious problem, except in a few isolated cases, and that the main factor in the causation of boils underground (apart from the predisposition to them of the individual—e.g., malnutrition, seborrhœa, &c.) is a high wet bulb temperature (75° and over) which at one and the same time indicates suitable conditions (warmth and moisture) for the vitality of the organism and opens the sweat glands and hair follicles and thus facilitates the entry of the staphylococcus.

CLINICAL AND LABORATORY NOTES

TWO CASES OF DOUBLE GALL-BLADDER.

BY PAUL CAVE, M.B. LOND., D.M.R.E.,

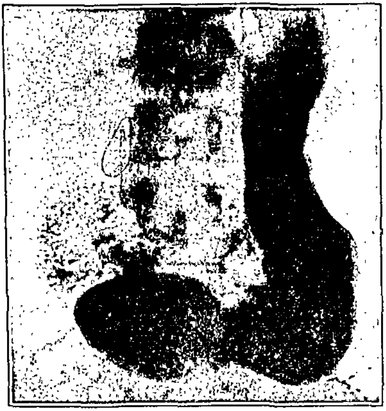
HON. RADIOLOGIST, ROYAL BERKSHIRE HOSPITAL, READING, AND BATTERSEA GENERAL HOSPITAL.

A DOUBLE gall-bladder is a rare developmental anomaly. A few cases have been found at operation and at post mortem, while only three have been discovered by radiography. All of these were reported in America. It appears that the following two cases are the first to be diagnosed by cholecystography in this country. From the clinical aspect they present no points of interest. Both were females aged about 40, with vague abdominal symptoms slightly suggestive of pathological gall-bladders. They are reported only because of the unusual radiographic appearance and on account of the rarity of the condition.

CASE 1.—Gall-bladder dye (Keraphen) was given by the mouth 16 hours before examination, and a barium meal was given at the time of examination. The stomach and duodenum were normal.

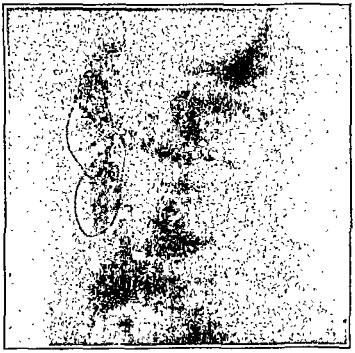
Two pear-shaped shadows are seen to the right of the second and third lumbar vertebræ (Fig. 1). The inner shadow is longer and wider and lies parallel with the spine. The axis of the smaller outer shadow forms a slight angle with the spine. The necks of both shadows converge to a point. On examination half an hour later the outer shadow was seen to be smaller and denser. Presumably this indicated reflex contraction of the outer vesicle. It was empty four and a half hours after the meal, while the inner vesicle still contained a residue of the dye. The lateral view (Fig. 2), taken at the first examination, shows that the inner vesicle lies slightly behind the outer vesicle. Their necks are on different levels, the distance apart being about the depth of one lumbar vertebra. The delayed emptying of the inner vesicle suggests that it may be pathological. The symptoms were, however, not severe and cleared up under medical treatment. No operation was performed.

FIG. 1.



CASE 1.—Antero-posterior view.

FIG. 2.



CASE 1.—Lateral view.

CASE 2.—*The same technique was followed as in Case 1,* but no barium meal was given.

The two shadows appear between the eleventh and twelfth ribs. In the antero-posterior view (Fig. 3) they overlap to a certain extent, so that the inner vesicle is partly obscured by the outer vesicle. The lateral view showed the inner vesicle lying (as in Case 1) slightly behind the outer vesicle. The inner vesicle emptied well after a fatty meal, but the outer vesicle contained a residue. This suggests that one gall-bladder may be pathological, but the symptoms were not severe enough to warrant an operation.

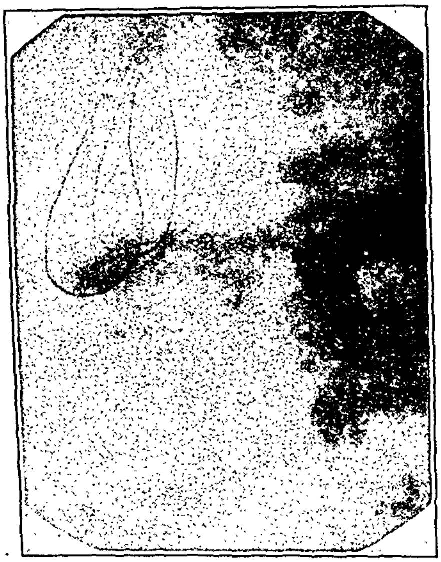
These two cases show a striking resemblance. Both patients had indefinite symptoms which were not severe enough to warrant operation. In both cases there was delayed emptying of the larger gall-bladder. Was one gall-bladder in each case enlarged as the result of chronic infection, or had it been larger than its fellow from birth? Does the presence of a double gall-bladder increase the risk of one or both becoming infected? Does the mutual pressure of the gall-bladders mechanically restrict the emptying of one of them, apart from infection? It is unfortunate that neither case was operated upon, as the result might have thrown light on these questions.

One may expect that, with the widespread use of cholecystography, other cases, both normal and pathological, will be recorded.

DISCUSSION.

The first mention in literature of a double gall-bladder occurs in "Philosophical Transactions" for the year 1693–94, where a certain Dr. Foot quotes a case of a woman, aged 31, having an enlarged liver and two gall-bladders, both distended with bile. He states that one gall-bladder was in the right lobe and one in the left lobe of the liver. In 1886 Purser[1] showed a case before the Academy of Medicine in Ireland. This was a girl of 11 years who had two gall-bladders, each with separate cystic ducts opening into the bile-duct. In 1911 Sherren[2] reported a case found at operation, in which the two gall-bladders were joined only along a narrow portion of their circumference and each possessed its own cystic duct.

FIG. 3.



CASE 2.—Antero-posterior view

More recently, Meyer[3] and Nichols[4] have also reported cases. In Meyer's case the two gall-bladders were joined over a broad area of their circumference and communicated by a narrow opening in their necks. A single cystic duct was present. Nichols's case was diagnosed before operation, as a radiogram showed a double cluster of stones. At operation the gall-bladders were found to be joined by connective tissue and each had its own cystic duct. Other similar cases are reported by Daever and Ashurst[5] and by Schachner.[6]

The first case of double gall-bladder diagnosed by cholecystography was reported by Climan[7] in America. The radiograms showed good concentration of the dye in both vesicles and normal reduction after a fatty meal. One gall-bladder lay behind and below the other. Both were reported as normal. Hayes[8] has described a similar case.

According to Boyden's[9] studies on 19,000 human subjects and 10,000 domestic mammals, the incidence of double gall-bladder is as follows: Humans, 1 in 3–4000; pigs, 1 in 198; sheep, 1 in 85; calves, 1 in 28; cats, 1 in 8.

The rarity of the condition in human beings accounts for the fact that Graham[10] did not find a single example in 1218 cases examined by cholecystography.

The mode of development of double gall-bladders is variously described by different authors. According to Keith,[11] the bud for the gall-bladder divides. Boyden, on the other hand, states that this mode only applies to cats and that in humans the supernumerary vesicles are derived either from the hepatic, cystic, or common bile-ducts. Boyden also describes another method of development which occurs chiefly in cattle and sheep: a vesicular outgrowth of liver trabeculæ enlarges to form a supernumerary gall-bladder. This type of development is the only one which can account for Foot's case of gall-bladders in the right and left lobes of the liver. Aschoff gives a completely different account. He states that normally the cells of the gall-bladder bud proliferate and give rise to a number of cavities, separated by septa. The cavities eventually fuse into one large cavity. When they fail to fuse, supernumerary gall-bladders are formed. With this type of development one would expect to find rare cases of gall-bladders having multiple cavities, and such have been reported by Daever and Ashurst,[5] Dévé,[12] and others.

The following classification of gall-bladder anomalies appears to be rational, as it is based on the supposed method of development, and is descriptive of the various types.

1. *Ductular gall-bladder.*—Derived from supernumerary vesicles from either the hepatic, cystic, or common bile-ducts. Two cavities are present, each having its own cystic duct.
2. *Bilobed gall-bladder.*—Formed by initial subdivision of the primitive gall-bladder bud. Two cavities communicate with the common bile-duct through a single cystic duct.
3. *Diverticular gall-bladder.*—Resulting from persistence of cavities and septa in the gall-bladder bud. One large cavity, communicating with one or more smaller cavities.
4. *Trabecular gall-bladder.*—A vesicular outgrowth of liver trabeculæ. Common in cattle and sheep, but of doubtful occurrence in humans. It would account for the presence of two widely separated gall-bladders.

A METHOD OF INSERTING CONTACT GLASSES.

BY R. AFFLECK GREEVES, F.R.C.S. ENG.,
OPHTHALMIC SURGEON TO THE MIDDLESEX HOSPITAL; SURGEON TO MOORFIELDS EYE HOSPITAL.

TWO communications have recently appeared in THE LANCET on the use of contact glasses, respectively by Mr. Rugg-Gunn[1] and Prof. Leopold Heine.[2] The former describes in detail what I conclude is the accepted method of inserting the glasses. The patient leans forward with his head in a horizontal position; the inverted contact glass, filled with saline, and kept level, is held by means of the rubber sucker in the surgeon's right hand, and is inserted between the lids which are held open with his left hand. By this method, to quote Mr. Rugg-Gunn, it is extremely difficult to avoid enclosing an air bubble between the eye and the contact glass; the air bubble is a sore trial because it may recur again and again, and there is nothing to be done but each time to take out the glass and start afresh. All this makes the preliminary trial of different glasses, which is essential in order to determine the fit and power required, extremely tedious to patient and surgeon. Prof. Heine criticises certain points in Mr. Rugg-Gunn's paper, but as he does not refer at all to the latter's description of the method of insertion, I take it that this meets with his approval.

---

[1] THE LANCET, 1930, ii., 1067.
[2] Ibid., March 21st, 1931, p. 631.

Although my own experience of these glasses is limited to one patient, who, as it turned out, could not tolerate them, I feel that it is worth recording, mainly because I very soon found it possible, by using a different method, to insert the glasses quickly and easily.

The particular patient on whom I tried the contact glasses was a case of bilateral conical cornea, whose vision could be improved from less than 6/60 to 6/12 in each eye by concave sphero-cylinders, which, however, she found great difficulty in wearing, as she said they caused headache and giddiness. When she was wearing suitable contact glasses 6/9 vision was obtained in each eye, but in spite of the fact that the glasses selected appeared to fit the scleral curves perfectly, the patient could not tolerate them for longer than an hour at a time, and as there was no improvement after daily trial for a fortnight, I decided to abandon the attempt altogether. The patient was a highly nervous woman, and therefore perhaps not altogether a suitable case; apart from this, however, on each occasion the glasses caused congestion and irritability of the conjunctiva, which began soon after the effect of the local anæsthetic had passed off, and gradually became so intense that the patient begged to have them removed.

METHOD OF INSERTION.

The surgeon stands behind or beside the patient, who may either lie on a couch with his head on a low pillow, or may sit in a chair which supports the head with a headrest; the latter position is, if anything, the more convenient. Cocaine or holocaine having been instilled into the eye, the patient is told to look slightly upwards and inwards, and the empty contact glass, held by means of the sucker in the surgeon's right hand, is inserted into the lower fornix, the surgeon depressing the lower lid slightly for that purpose with his left thumb. With his left hand the surgeon now steadies the patient's upper lid in order to prevent blinking, and while he holds the contact glass close to the globe, but not quite against it, with his right hand, an assistant allows saline to drip from an undine into the space between the contact glass and the globe. The space becomes quickly filled (the fluid remaining in it by capillary attraction), and when this is accomplished the surgeon gently applies the contact glass to the globe, at the same time allowing the upper lid to fall over the upper margin of the glass. Removal of the sucker concludes the operation. This method not only obviates the formation of air bubbles, but can be repeated with rapidity and ease, so that a large number of glasses can be tried in succession in a very short space of time.

The only objection I can see to this method is the fact that the help of a second person is required, but although I did not actually try it, I have little doubt that it would be possible, with practice and dexterity, both to hold the upper lid with the little finger of the left hand, and at the same time to drip the saline from a conveniently shaped undine or pipette held in the palm of the hand, while holding the contact glass in apposition to the eye with the right.

When the patient finally inserts the glass himself, he must of course do it with his face in the horizontal position, looking downwards. One thing which surprised me was the comparative ease with which my patient eventually inserted the glasses herself, and that in spite of a very shaky hand. It is true that she never accomplished the feat without enclosing an air bubble, but I think that with a little more practice she would have done so.

With regard to the removal of the contact glass, I found that this was most safely accomplished by reapplying the sucker, and by slipping the glass off sideways to the outer side, while the patient looked in the opposite direction.

In the management of the case I received valuable assistance from Mr. E. F. King, one of the house surgeons at Moorfields Hospital, with whose help I evolved the method of insertion described above, and who inserted the glasses on the days when I did not attend at the hospital.

REMISSIONS AND RELAPSES ASSOCIATED WITH PREGNANCY IN MYASTHENIA GRAVIS.

BY L. P. E. LAURENT, M.B., M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, THE HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

THE influence of pregnancy, and sometimes of the menstrual cycle, on the course of myasthenia gravis lends support to the view that this condition is largely, if not entirely, brought about by endocrine disturbances.

Grosse[1] has reported a case in which symptoms first developed during pregnancy and recovery took place after the induction of premature labour. Tilney[2] has also seen myasthenia gravis begin during pregnancy, and similar observations have been made often enough to exclude the possibility of chance. In contrast to this, remission of symptoms during pregnancy has been observed in many cases. Goldflam's remarkable case, in which three pregnancies were accompanied by remissions while parturition was on each occasion followed by a relapse, is one example. Of equal interest is Fearnsides's case[3] reported in 1916. The history of the latter, which is detailed below, shows a complete remission of symptoms during the first and second pregnancies and serious relapses in five subsequent pregnancies. The literature contains many cases of myasthenia gravis which have been observed for periods of 12 to 14 years. The cases with the longest histories are those of Collier[4] (two cases, 24 years each) and McKendree[5] (19 years). The case reported below has had undoubted symptoms of myasthenia for 29 years, and she has been under medical observation for 26 years.

A married woman, aged 40 years, was admitted to the Hospital for Epilepsy and Paralysis, Maida Vale, in 1916, under the care of Dr. George Johnston. She was presented by the late Dr. E. G. Fearnsides to the Neurological Section of the Royal Society of Medicine. The following account of the patient's history is in part reproduced from Dr. Fearnsides's notes.

Since 1899 she had suffered from typical attacks of major epilepsy, seven to eight attacks occurring annually. In 1902, while still single, she one day noticed difficulty in speaking and on the next day she complained of severe headache and dysphagia. These symptoms cleared up in the course of a few days, but have since recurred to a varying extent on many occasions. About Christmas, 1903, she was in bed for the six days preceding her wedding, owing to the weakness of the arms and legs; this subsequently disappeared completely. She was in good health whilst carrying her first child, who was born in February 1905, after a remarkably rapid labour. She first came under observation in 1905 at the London Hospital, when six months pregnant of her second child.

In 1905 she weighed 8 st. 7 lb. No abnormal signs were detected in the heart, vessels, lungs, abdomen, and urine. No enlargement of the thyroid or thymus could be detected clinically. She complained of failure of the voice after talking for some time, dysphagia, diplopia, and unilateral right-sided headache which came on in attacks, preceded by a pricking sensation starting in the left foot and spreading upwards over the whole body. On examination the positive findings were as follows: The voice was nasal. The speech tired easily, the voice disappearing completely in the course of conversation. Ptosis was present occasionally. Varying degrees of external ophthalmoplegia were observed at different examinations. Weakness of the orbicularis oculi was constant. Whistling was impossible and the cheeks could only be blown out for short periods. The palate moved well at first but ceased all movement after five to ten deep breaths. Protrusion of the tongue, normal at first, became impossible after 5 to 15 repetitions. Dysphagia of varying intensity was present, nasal regurgitation taking place when she was at her worst. The limb musculature tired easily and the myasthenic electrical reactions were obtained. At times she found walking impossible.

On Jan. 28th, 1906, she was delivered of a healthy daughter after a rapid labour. Towards the end of the pregnancy there had been a complete remission of all symptoms. Dysphagia, diplopia, and nasal voice recurred on the eighth day after delivery. A gradual improvement took place later. In 1907 she had a six-months miscarriage. Relapse occurred at the beginning of this pregnancy. Nasal regurgitation and dyspnœic attacks were particularly frequent in the later months of pregnancy. Miscarriage was followed by a gradual improvement.

In 1909 a five-months miscarriage of twins again brought to an end a severe relapse which had taken place during pregnancy.

In 1914, when six months pregnant, she was unable to sit up in bed, and suffered from nasal regurgitation and dyspnœic attacks. On this occasion the artificial termination of pregnancy was followed by a rapid improvement. In 1922 she had a five-months miscarriage, and in 1926 another at three months. She relapsed again during the pregnancies, and improved considerably after miscarriage, particularly since 1926, as will be seen from the account of the present condition given below.

On Jan. 31st, 1931, she was a stout woman weighing 12 st. 7 lb. Her face had a fatigued expression but at rest no special muscle group could be incriminated. There was a slight degree of ptosis, easily compensated by overaction of the frontalis and not increasing with exercise. She had not experienced diplopia during the last four years. On examination the ocular movements, at first of full range, soon became impaired on repetition. Upward movement of the right eye and outward movement of the left eye were most affected, strabismus and diplopia resulting. Bilateral facial weakness was revealed when she attempted to retract the upper lip, and there was definite weakness of the orbicularis oculi, closure of the eyes being impossible when the slightest resistance was offered. The tongue could not be protruded more than half an inch beyond the teeth, but repetition of that movement ten times did not give rise to fatigue. There was no wasting of the tongue. There had been no dysphagia and no dyspnœa for four years. Of the muscles of the limbs and trunk, only the deltoids tired in the course of examination. She walked up and down three flights of stairs, talking volubly all the time, and experienced no difficulty beyond slight dyspnœa, within normal limits for a woman of her age and stature. The tendon reflexes were all present and rather brisk, and the plantar responses flexor. No abnormality was detected in the chest or in the abdomen. The thyroid and the thymus showed no signs of enlargement on clinical examination.

She menstruates regularly, her periods lasting three days and recurring every three weeks—her normal cycle. It is interesting to note that the intensity of symptoms has never had any relation to the menstrual cycle, although it has been so obviously related to pregnancy. The miscarriages are satisfactorily accounted for by a prolapsed uterus, for which she underwent colpoperineorrhaphy in 1928.

The ease and rapidity of labour noted in this case has already been reported in myasthenia. In Tilney's case, already referred to, labour lasted five hours and a half in a primipara, and I have notes of a case of myasthenia gravis in which a first labour was completed within five hours of the onset.

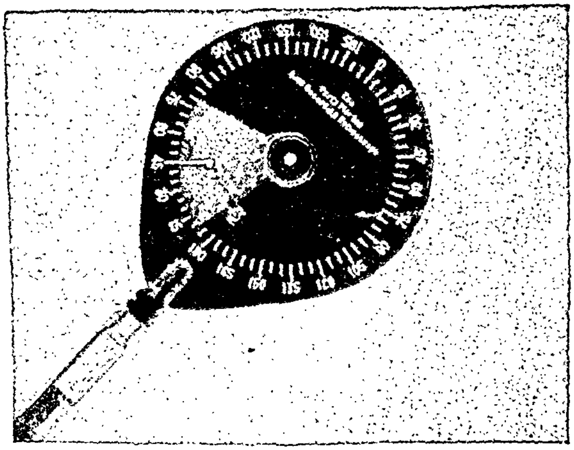
NEW INVENTIONS

AN IMPROVEMENT IN RETINOSCOPES AND OPHTHALMOSCOPES.

THE purpose of this device, shown in the illustration, is to make retinoscopes and ophthalmoscopes self-recording by means of an apparatus for registering the meridians in retinoscopy. At the back of a retinoscope or ophthalmoscope and along its circumference are marked a scale of the various meridians. At the back also there is attached a section movable about a pivot situated around the aperture in the centre. This section is in the form of a triangle with its base slightly curved and carrying with it an indicator which serves to make the above-mentioned scale of meridians at the circumference. Furthermore, this triangular section is conveniently weighted so that it will move in accordance with the position of the retinoscope or ophthalmoscope when in action, but comes to rest when the instruments are tilted forward for the purpose of noting the position of the indicator on the scale of meridians. In this connexion a spring and knob may be utilised, or any other suitable device, to lock the indicator in position.



The manufacturers are The Elliott Optical Co., Ltd., 104–5, Great Saffron-hill, London, E.C.

R. S. McCLELLAND, M.D., Ch.B. Edin.

LONDON LOCK HOSPITAL.—The Lord Mayor of London recently opened an extension of this institution in Dean-street, Soho. The enlargement, which has cost over £22,000, of which some £5000 remains to be raised, includes new consulting-rooms, a new dispensary, a new intermediate treatment department, and a dining-room for the staff. Last year there were 90,000 out-patient attendances.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF COMPARATIVE MEDICINE AND EPIDEMIOLOGY.

AT a combined meeting of these Sections held on March 25th, with Prof. G. H. WOOLDRIDGE, F.R.C.V.S., in the chair, a discussion on

Milk-borne Epidemics Due to Streptococci

was opened by Dr. W. G. SAVAGE. Streptococci, he said, were extremely common in milk, and were derived from many sources. Their presence, even in very large numbers, was no evidence that the milk so infected was harmful. Even the demonstration of hæmolytic streptococci, he declared, was inadequate evidence of potential infectivity, and it was difficult to give any series of tests of a bacteriological nature by which to determine the infectivity of the streptococci in milk. On the epidemiological side, however, the ground was more definite, for two types of infection, both due to streptococci, had been shown many times to have been propagated by milk consumption. These types were scarlet fever and angina (sore-throat), and they were met with in various degrees of malignancy. The possibility of a human and a bovine origin had to be considered in regard to both. In 1912, after examining all previous records of alleged bovine scarlet fever, he arrived at the conclusion that the cow was the probable carrier of the organism in these epidemics, but in a purely passive capacity, showing in itself no disease symptoms. The view that the Hendon outbreak was spread by locally infected cows explained all the essential facts and reconciled conflicting ideas. The next investigation along this line was made 16 years later by F. S. Jones and R. B. Little on a scarlet fever outbreak in New Jersey State, U.S.A. Here were scarlet fever cases on the farm, but one of the cows was found to have an injury to the teat and suffered from mastitis being present with abundant hæmolytic streptococci of the human type in the secretion. It was found possible to infect other quarters of this cow, as well as another cow, with the streptococcus and to set up severe mastitis. In another paper Jones stated that milk which had been heated to 58° C. for 20 minutes, or which was passed through a coarse Berkefeld filter, had the ability to inhibit the growth of the scarlet fever streptococcus. This, said Dr. Savage, confirmed his view that in milk-spread scarlet fever the agency of an infected cow must be considered possible.

In epidemics of angina the epidemiological facts were these. From 1890 to 1910 a number of outbreaks, all milk-borne, were reported in Great Britain. A typical example was that at Colchester in 1905, when 96·6 per cent. of the 600 cases were traceable to the milk of one distributor, who received his milk from five sources. On one of the farms a cow was found to be suffering from streptococcal mastitis. Exclusion of this animal's milk from the town's supply caused the epidemic to cease. It was remarkable, he said, that since 1910 there was no reported milk-spread angina until the Hove outbreak of last year. In the United States no outbreaks were reported until 1911 but many since then. C. L. Scamman enumerated 87 milk-borne outbreaks of scarlet fever between 1893 and 1928, and 45 milk-borne outbreaks of septic sore-throat between 1908 and 1928; 55 per cent. of the latter were attributed to a milk handler, 30 per cent. to a diseased cow and a milk handler.

Much work had been done to elucidate the bacteriology of bovine mastitis and the cause of these anginal outbreaks. In 68 per cent. of his cases of bovine mastitis (1906–09) he found the *Streptococcus mastitidis;* he then discovered this strain in quarters clinically sound in 84 per cent. of cases, these quarters rarely being subsequently involved, while to naked-eye appearance the milk of these quarters was unaltered. He found that the bovine type of streptococcus was non-pathogenic to mice, and to laboratory animals generally it was of low virulence, though it readily set up mastitis in goats when introduced into the teat canal without damaging the mucosa. The human types were pathogenic to mice. He felt so sure that *S. mastitidis* was not a cause of human disease that on two occasions he swabbed his own throat with massive doses of it from a recent case of cow mastitis, and suffered no effects; it was moreover difficult to recover, showing that the human throat was an alien habitat. From these and other experiments Dr. Savage in 1911 elaborated the hypothesis that ordinary bovine mastitis and teat lesions were harmless to man but that occasionally the local infection was due to implantation of organisms of human origin. The cow in this class of infection is only potentially pathogenic to man when it acts as an active or passive carrier of organisms of *human* origin. All subsequent work has tended to confirm the truth of this hypothesis. In an outbreak of sore-throat in Chicago in December, 1911, and the following month, in which over 10,000 persons were affected, D. J. Davis had emphasised the point that hæmolytic streptococci were responsible, differing from the type associated with bovine mastitis. Davis and Capps had shown experimentally that hæmolytic streptococci of human origin, when introduced into the cow's udder in large numbers by means of a catheter, could produce mastitis.

Dr. Savage expressed the hope that later speakers would say whether they were satisfied that existing methods were adequate to distinguish definitely between types harmless to the human, and those which set up in man angina or scarlet fever. Ample evidence was available that milk could be a vehicle for two kinds of streptococcal infection—namely, scarlet fever and angina. It seemed clear that the cow only served as an infective agent when the streptococci were initially of human origin, implanted on the cow's teats, or introduced into the udder.

BOVINE MASTITIS.

Mr. F. C. MINETT, M.R.C.V.S., spoke particularly of streptococci in bovine mastitis indistinguishable from the human *Streptococcus pyogenes.* As in many outbreaks of disease suspicion fell on the cow, it was important to consider the infections of the milk-producing organs. For the present discussion, as well as agriculturally, the most important of these was the mastitis due to streptococci. It was very prevalent. At the Royal Veterinary College, Camden Town, there had been occasion so far to examine, by blood-agar plating, milk samples from 1103 cows belonging to 20 herds. Of these cows 444 (or 40·2 per cent.) showed infection in at least one quarter of the udder, the incidence varying between 11 and

65 per cent. in the various herds. In the great majority a streptococcus was present. Five of these herds would have been classed as "clean." In most cases the disease was occult, no changes were obvious in the milk, and clinical examination was inconclusive. Mastitis in cows could be caused by hæmolytic or non-hæmolytic streptococci, but on the present occasion there was need to consider only the kind referred to by J. H. Brown as beta *hæmolyticus*—i.e., those which produced a distinct zone of clearing around deep colonies in blood-agar plates. There were, said Mr. Minett, three characters common to the great majority of udder hæmolytic strains, and these features served also to distinguish them from *S. pyogenes* of human sources. The first was their lack of pathogenicity for laboratory animals such as mice and rabbits, and the fact that they were not dangerous to man. Secondly, when grown in lactose broth for five days, considerable quantities of acid were produced, so that the final pH came to rest at 4·4 to 4·8. The third character was the ability of udder streptococci to hydrolyse sodium hippurate to glycol and benzoic acid. Up to the present time his laboratory had been in touch with 13 cases of mastitis whose udder secretion had yielded hæmolytic streptococci with characters different from those of cocci ordinarily found. In at least nine of those cases the streptococci appeared to be the cause of the mastitis, their numbers varying from several hundred thousand to eight millions per c.cm. These strains were exceptional in the relatively large amounts of hæmolysin they produced, and their high pathogenicity to mice and rabbits. No other conclusion seemed possible than that in these cases the cow's udder was infected with streptococci from a human source, very likely from the milker; yet seldom could human disease be identified. The power of these particular strains to produce mastitis had been tested by injecting 1 c.cm. of a 24-hour serum broth culture into the udder of a lactating cow via the teat canal; an acute mastitis ensued, leading to a drying up of the milk secretion and atrophy of the quarter during the third week.

Dealing with the part played by the cow in milk-borne streptococcus epidemics, Mr. Minett said that the hypothesis which Dr. Savage put forward in 1911 (and which he had repeated to-day) was suggestive, and the investigations which had been carried out in America could be held to have proved that the cow had played a major part in some of the epidemics. At the moment the important question was whether the proportion of outbreaks in which the cow was to blame was large or small; his own view was that the extent of the danger was usually under-estimated, and for this view he gave a number of reasons. Why did not such outbreaks occur more frequently? He suggested that their rarity might be not solely due to the fact that most udder streptococci were of the bovine type, but might be due in part to the fact that the human hæmolytic streptococci, which were not infrequently implanted in the udder, were of a type or in a life-cycle phase which was relatively harmless to man. Even when the streptococci in the udder were of a type known to be harmful to man, they did not always cause epidemics.

In conclusion he emphasised the desirability of defining more clearly the part played by the cow. The initiative must rest with the medical officer who was brought into touch with the outbreak. If, when a particular farm could be incriminated, the medical officer would communicate with the Research Institute of the Royal Veterinary College, the opportunity of making a bacteriological examination of milk samples from the cows would be welcomed. Their findings could then be correlated with those of the medical bacteriologists.

THE HOVE OUTBREAK.

Dr. E. **WILKINSON** (representing the Ministry of Health) said that in the recent Hove outbreak a considerable time elapsed before the matter was brought to the notice of any health authority, and so the investigations were begun at a late stage. Clearly that was a case in which human streptococci had been implanted into the milk channels of the cow. Enormous proliferation occurred and lasted several weeks, in fact about the same time as an epidemic of tonsillitis. In this Hove outbreak over a thousand cases occurred, and more than sixty deaths. Not until the end of December, though cases of tonsillitis were reported months earlier, was it reported that nearly all these patients were customers on one particular milk round. Samples of milk were found to be crowded with streptococci. There was strong reason for suspecting that the origin of the Hove epidemic was outside this country, as a bailiff of the farm had been visiting a house of illness and had probably brought the infection to the farm. This bailiff had certainly been in contact with cases of tonsillitis.

Mr. A. W. **STABLEFORTH**, M.R.C.V.S., spoke on the possibility of finding a method of distinguishing bovine from human streptococci by serological methods. He had examined 104 strains of streptococci from the bovine udder, and had more recently compared these with 50 strains of human origin. Of 46 bovine strains of hæmolytic streptococci which he examined, 25 fell into one very definite type similar to that of human *hæmolyticus*. Sixteen beta hæmolytic strains were notable for the fact that they caused wide zones on blood-agar plates, and caused a marked degree of lysin in broth, and were pathogenic. The beta hæmolytic strains which he examined had common group antigens, and were distinct from other bovine strains which he had examined. They also showed some common group agglutinins with human strains of *Streptococcus pyogenes*. The majority of streptococci from the bovine udder were distinct from human streptococci, but there occurred in the bovine udder members of the group which had some antigens in common with streptococci of human origin. The likeness he had observed was only a group likeness, not a specific one.

Prof. G. H. **WILSON**, M.D., referred to the Hendon epidemic, and remarked that the disease broke out later in Wiltshire, where cases of septic sore-throat occurred. It was highly probable, he thought, that streptococci from the throats of human carriers on the farm were implanted on the ulcers of the cows teats. He referred to two cases in which cows' teats yielded the diphtheria bacillus. Milk-borne epidemics or outbreaks of septic sore-throat and scarlet fever seemed to have been less common during the last 20 years than formerly.

Mr. **SIDNEY VILLAR**, F.R.C.V.S., said he was conversant, as the veterinary surgeon concerned, with the Hendon outbreak, and he agreed with Dr. Savage that the cow was a passive carrier. The cows concerned in that epidemic did not suffer from mastitis as ordinarily understood; they were infected with cow-pox, but not true variola. The vesicle was broken down by milking, and continued milking resulted in severe ulceration; 50 of the 70 cases concerned in the Hendon outbreak had teat sores. In the home of one of the milkmen a girl had scarlet fever. As there were few human cases of infection from milk, and cow mastitis was very common, he did not think the latter could constitute a great danger to the human subject. It was customary to discard milk which came from the infected quarter and to use the milk from the remaining three-quarters, if inspection showed it to be apparently sound.

Dr. **Wilkinson** referred to an epidemic in which investigation revealed that some people in the neighbourhood had scarlet fever, others tonsillitis, while from some who were tested there was obtained a hæmolytic streptococcus though they had no symptoms; the latter included the proprietor of the milk business who subsequently desquamated.

The **Chairman** agreed that it was fair to implicate the sores on the teats of cows in these epidemics, even when there was no actual mastitis. This teat condition was very common in cows; it was a form of impetigo. Cows frequently showed the teat condition soon after calving. He was once an unwilling demonstrator, among others, of the truth that milk even with a high content of streptococci from cows with mastitis was non-infective. He was one of eight persons who were drinking milk from a particular cow. One day he noted an unusual salty taste, and on investigation the milk was found to be teeming with streptococci. Yet no illness followed.

REPLY.

Dr. **Savage** expressed his gratification that the views he advanced in 1911 were now accepted as current knowledge. He considered that one important factor determining whether an epidemic would occur was the dosage of the virus or microbe. In one case he found that when the dilution of the milk from the infected farm fell below a certain figure, no fresh cases of human infection occurred.

SECTION OF UROLOGY.

At a meeting of this Section on March 26th, Mr. S. A. **Macdonald**, the President, took the chair, and a demonstration on principles and new advances in

Excretion Urography

was given by Prof. A. **von Lichtenberg** (Berlin).

The study of over 2000 cases and of seven intravenous contrast substances had, he said, enabled him to formulate the scientific principles of excretion urography. Five of the contrast substances were now reported for the first time; of these D40 (uroselectan B) had decided advantages; its administration was well tolerated, and excellent visualisation of the urinary tract was obtained after injecting 15 g. dissolved in 20 c.cm. of water. The new method had greatly clarified conceptions of the pathology of the urinary tract. Besides revealing anatomical changes, it gave a picture of the disease in all its physiological details. The urinary tract could be studied as a physiological entity; "system pathology" rather than "organ pathology" could be stressed. It was important that the eliminated quantity be enough to give satisfactory visualisation. The absolute quantity of the substance eliminated had no great influence on its applicability for excretion urography; its usefulness depended neither on the proportion eliminated through the kidney nor on the distribution in the body. It was important only that the quantity eliminated through the kidneys appeared in the urine as quickly and as concentrated as possible. The accompanying diuresis played an important part, since it influenced the concentration of the substances in the urine. Of the two substances on the market—abrodil and uroselectan—86 per cent. was eliminated in the urine, and of the other new substances tested—D34, D40, D50, B1015, and Sch122—the proportion secreted varied from 56 per cent. upwards. Of D40, 64 per cent. was eliminated, the maximum appearing half an hour after administration and elimination continuing for eight hours. The highest concentration of abrodil and uroselectan occurred three quarters and one and a quarter hours after injection respectively. The highest concentration was achieved by D40, 15 g. of which produced a concentration of 7·94 per cent., whereas 30 g. of uroselectan only produced a concentration of 4·4 per cent. The diuresis with D40 was 84 c.cm. at the first hour and 282 c.cm. in four hours, whereas with abrodil and uroselectan the figures were 175 c.cm. and 495 c.cm.; 120 c.cm. and 650 c.cm. respectively. The kidney capacity did not depend entirely on physical factors; chemical qualities also played a part. This was shown by the relation between the molecular weight of the substance injected and the concentration of the resulting urine. A large amount of iodine was not necessary for excretion urography; D40 contained about a fifth of the iodine that had previously been necessary. Good solubility and high iodine content were only relatively important; the absolute usefulness of the substances rested on a group of factors, some of which were still unknown. Work was being done on the isolated kidney in an attempt to improve the substances and discover these factors. Apart from toxicity, the most important element seemed to be elimination; not the amount given, but the amount eliminated determined success.

CLINICAL APPLICATION.

Dr. P. B. **Hughes** showed a large series of X rays from Prof. von Lichtenberg's clinic comparing pyelograms and excretion urograms and showing clearly that pyelography is apt to reveal a pelvis distorted by the pressure of the injection, while excretion urography shows the normal pelvis and its constant changes under the influence of peristalsis. The excretion method failed, however, when the kidney was damaged in the glomerular region. Purulent infection inhibited visualisation by this method, which was therefore a means of testing the function of the kidney. Thus anatomy and physiology, pyelography, and excretion urography, completed each other. Both failed, however, when a mechanical factor made filling from below impossible, and at the same time a physiological factor prevented filling from above. There were three groups of cases in which excretion urography gave exceptionally good visualisation, while instrumental pyelography failed to give the necessary information. In some of these the catheter method failed altogether; in others it gave defective pictures, and in others it caused diagnostic difficulties which could be cleared up by the complementary method. Pyelography failed, for instance, in cases of tumour with ureteral obstruction, but excretion urography showed the enlarged and deformed pelvis. Pyelonephrosis was shown by spherically dilated and fixed calyces. Excretion urography helped the surgeon to decide whether to adopt conservative or radical methods, as it gave an estimation of the function and emptying power of the kidney. In another group of cases the irritating fluid of the pyelogram might cause local cramp, so that one calyx perhaps remained unfilled; the fluid injected intravenously was not irritating, and could, therefore, fill all parts of such a kidney. In tuberculosis it might be impossible to get a catheter in, and even cystoscopy might be dangerous. Excretion urography was, therefore, particularly welcome.

If no visualisation of the kidney was obtained, and tubercle bacilli were found in the urine, no further investigation need be made. In hydronephrosis pyelography would not give a true picture of the size of the pelvis on account of irritation, but excretion urography showed it exactly, together with all the phases of emptying.

URETER, BLADDER, AND ADNEXA.

The normal ureter was never completely outlined by excretion urography on account of peristalsis. The whole tube was only seen when peristalsis was impaired or retarded. The interpretation of ureteral pyelograms was still unsatisfactory, and excretion urography was therefore particularly helpful. It would even show the slight changes produced by the passage of a small stone. It revealed slight degrees of atony and irritation. It distinguished between an actual kink and one that might be produced by a catheter in the pyelogram. A real kink was always seen in the same place in any number of excretion urograms. If the ureter was fixed, it failed to show pendulum movements, though its peristalsis might at first be unimpaired. Excretion urography showed up many stones that were not seen on an ordinary X ray, and the X ray showed stones which excretion urography did not reveal. Adnexal disease produced characteristic changes in the ureter. In prostatitis a slight atony of the ureter was revealed by filling of the lower part without dilatation. Later this went on to dilatation and tortuosity. Both sides were affected, but not necessarily equally. It was often possible to avoid cystoscopy and catheterisation if excretion urography were used in prostatic hypertrophy. A very dilated ureter might empty well, provided there were no obstruction lower down the tract.

The method was also useful for the bladder; carcinoma of the prostate would show as a displacement of the shadow with retention in the ureter and concentration at the point of torsion. Diverticulum of the bladder was well shown.

Mr. FRANK KIDD said that D40 would shortly be on the market in 20 c.cm. ampoules. He congratulated the Society on the honour Prof. von Lichtenberg had done it in electing to make the first announcement of his important discovery in this country at a meeting of that Section.

TUBERCULOSIS ASSOCIATION.

A MEETING of this society was held at Oxford from March 26th–28th, and will receive extended notice next week. After the annual meeting on the 28th, at which Prof. S. LYLE CUMMINS was re-elected president, a cinematograph film was shown illustrating

Thoracoplasty.

The film, taken by Messrs. Kodak, is divided into two parts, and shows the various stages of the operations of phrenic avulsion and thoracoplasty as performed by Mr. H. Morriston Davies. The accompanying legends explain each stage of the various procedures, as described by Mr. Davies in his book "Surgery of the Lung and Pleura." Mr. Davies relies entirely upon local anæsthesia in performing phrenic avulsion, 10 c.cm. of a 1 per cent. solution of novocain with adrenalin being sufficient to infiltrate the superficial and deep tissues, while in performing thoracoplasty he uses just enough chloroform to make the patient unconscious. A 1 per cent. solution of novocain with adrenalin hydrochloride 1 in 1000 is used for the local and regional infiltration.

Gelatino-thorax.

DR. J. CROCKET, in a paper on Gelatino-thorax, said that the introduction of oil or paraffin into the thorax had serious disadvantages, since they must be regarded as foreign bodies. Thus, in apicolysis, an operation now seldom performed, the paraffin used was extruded or formed a nidus of infection. He admitted that oleothorax was useful in stiffening the mediastinum, but in general he had found it disappointing. His patients brought up the oil through the bronchi, complained of its weight, or suffered from dyspnœa, digestive troubles, or effusions. A substance was required which, being of animal origin, would freely intermingle with a fluid effusion if present, and likewise an antiseptic that would act in the presence of serum. Such a combination was gelatin 2–5 per cent. with neutral Acriflavine 1 in 2000 to 5000. The acriflavine could be safely left in closed cavities, and its antiseptic effects, which greatly exceeded those of perchloride of mercury or phenol were increased in the presence of serum. Whereas Gomenol had been found to have no marked effect upon the tubercle bacilli in effusions, acriflavine greatly reduced the bacterial content. His technique was as follows: the gelatin was dissolved in normal saline and sterilised in an autoclave. The neutral acriflavine solution was boiled. The mixture should be freshly prepared for each case. It was desirable to test the idiosyncrasy of each patient and give small doses—e.g., 10 c.cm. at first. He used a blood-transfusion syringe with a two-way stop and rubber tubing arranged so that the effusion could be withdrawn and the gelatin-acriflavine solution be injected through the same needle. The gelatin was heated to 103° F. and injected slowly through a small needle and well below the level of the fluid, if this was not drawn off; 10 to 20 c.cm. were given at first, and if no reaction occurred the amount was increased to 200–300 c.cm. He had had several cases where no further injections were required after a single dose of 2–6 oz. An alternative method was to empty the pleural cavity, replace the fluid with air, and then inject the gelatin and acriflavine. After each syringeful the pressure should be noted, and should ultimately be below zero level. At the conclusion of the injection, pressure should be made at the site of puncture, the patient should lie on the opposite side, and avoid talking and coughing. The outstanding indication was an effusion rich in tubercle bacilli or secondarily infected, with fever, &c. It was also useful when there was a cavity, to sterilise a pleural cavity before thoracoplasty, and in basal bronchiectasis. He did not favour interference where there was an effusion and no symptoms, believing this to serve as a good natural splint.

In the subsequent discussion, Dr. M. GILBERT (Leysin) agreed about the disadvantage of oil in not mixing freely with the pleural contents, but defended oleothorax as a valuable procedure in suitable cases. Secondary infections of the pleural cavity were not its best indications. In eight years' experience he had never had a perforation of lung, and considered this due to faulty technique. A too high pressure in malignant pleural effusions was apt to enlarge existing perforations. He had found oleothorax to decrease the bacilli in effusions. A further advantage was the ability to see the formation of fluid when oleothorax was used for obliterative cases.

The session concluded with an exhibition and demonstration of radiograms by Drs. G. T. Hebert, G. Jessel, and A. J. Morland.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this Institution on March 10th, with Mr. G. C. E. SIMPSON, Vice-President, in the chair, a paper on

Removal of Tonsils and Adenoids

in subacute rheumatic heart disease was read by Mr. P. W. LEATHART. The 50 cases chosen for operation were in-patients at the Liverpool Heart Hospital. All showed fever for a long period before operation, and one or more cardiac lesions. Operation was performed on the assumption that the patient was a carrier of the infection in his tonsils and adenoids. On this assumption the size of the tonsil was not important; the presence of enlarged glands in the anterior triangle of the neck was more significant inasmuch as it was clinical evidence of absorption of poison. Removal of the tonsils could do no more than prevent further absorption. The patients had been under observation for long periods, sometimes as long as four years. In 16 cases the temperature finally became normal and stayed normal; in 20 the cardiac condition became stationary; in eight there was improvement in it; in the rest it was not possible to give an opinion; in all except one the relatives were emphatic that the general health had improved. The question arose, said Mr. Leathart, whether the tonsils were front-line barriers to infection, or open doors for the purpose of admitting disease. The latter view was the more reasonable for it was known that all tonsils and other external lymphoid masses such as Peyer's patches and solitary follicles contained organisms even in health. It was probable therefore that in health poison was being absorbed from them, the object being to establish or keep up immunity. If the immunity was at a low ebb or failing, more poison was absorbed than could be dealt with, and the patient was in danger. In such cases if there was evidence, such as enlarged cervical glands, that the tonsil was the open door through which poison was entering, the door should be shut by its removal.

Mr. COURTENAY YORKE pleaded for a more conservative attitude towards the tonsils. He thought local infection in the tonsil a very uncommon cause of systemic disease, and he believed that the tonsils were sacrificed far too often in the mistaken belief that they were centres of auto-infection. The tonsillar crypts were lined by stratified epithelium which afforded an effective barrier to infection. The presence of cheesy material in the follicles was very common and could not be regarded as pathological. In adults the operation of tonsil dissection, under a general anæsthetic, was a severe one and fraught with obvious dangers. It should therefore be performed with caution, especially in the type of case where the tonsils were condemned on the supposition of auto-infection.

Mr. H. V. FORSTER was doubtful whether the lymphadenoid tissue of the pharynx and post-nasal space was really an open door through which the individual invited combat and was content to prove victorious or to be eliminated on the result of the fight. It would be better, of course, that the invader should be arrested in a front-line engagement, rather than admit a serious conflict with the deeper-placed reserves, and it was interesting to know that Kaiser had recently recorded how in a large group of American children deprived by operation of the familiar masses of lymphadenoid tissue of the upper respiratory and food passages, there was a greater incidence of bronchitis and pneumonia than in controls.

Dr. ISAAC HARRIS testified to the accuracy of Mr. Leathart's findings. There were some cases, he said, which without a shadow of a doubt benefited by tonsillectomy; there were others in which we might be equally sure that the operation was useless. In the great majority of cases it was difficult to say one way or the other. The important thing was that some cases of rheumatic heart certainly derived considerable benefit from the operation. The danger of operating was easily exaggerated. As long as there was no gross damage of the heart muscle the cardiac case usually stood an operation as well as the normal case.

Mr. E. MALCOLM STOCKDALE held that the structure of the tonsil was such that it constituted a weak spot, readily becoming infected and liable to disseminate disease. Few people escaped an attack of tonsillitis. As the treatment of adenoid and tonsil disease had progressed, the number of cases of enlarged glands (tuberculous) in the neck had greatly diminished, as also had Pott's disease of the spine. The size of an infected tonsil was no indication of its power for evil, a small red buried tonsil being more dangerous than the greatly enlarged pale protruding tonsil.

Technique of Inhalation Anæsthesia.

Dr. R. J. MINNITT read a paper in which he described the McKesson Nargraf apparatus and explained the technique of inhalation anæsthesia with the face mask, and also with de Caux's intratracheal catheters. He had had experience in over 200 cases, including almost every kind of operation. The advantages were the comfort and speed of induction, the minute quantities of ether used, the absence of cyanosis, the speedy recovery, the reduction of post-anæsthetic vomiting, and of the taste or smell of ether, and the freer atmosphere in the operating theatre from ether exhalations. The evidence, he said, was much in favour of rebreathing, the addition of carbon dioxide to the anæsthetic gases, and the elimination of ether as far as possible in renal disease.

Dr. JOHN HALTON inquired what preliminary medication Dr. Minnitt gave before gas-oxygen anæsthesia; he thought that the success of any anæsthetic depended largely upon the patient's condition immediately before the induction. He had recently perfected a technique which for open ether anæsthesia required the average use of only 8–12 oz. of ether for the first hour of major operations. In roughly 300 recent cases in which the anæsthetic was administered in this way as a hospital routine, compared with 100 by ordinary methods, the difference in post-operative comfort and absence of complications was very marked.

Mr. H. C. W. NUTTALL supported the statements made about the efficiency of the McKesson Nargraf apparatus and the absence of post-operative respiratory complications. Provided cyanosis was avoided there was probably no greater hæmorrhage than with open ether, but this question was difficult to decide, for patients varied whatever type of anæsthetic was used. He thought that if this method was found to be superior to others in hospital then its use must be extended to private practice, but here its cost and the bulk of the apparatus raised difficulties. He did not agree that it should be reserved for specially difficult cases; routine use with all types of case was essential for perfecting technique.

Dr. W. J. BENNETT JONES remarked that Dr. Minnitt had mentioned gas and oxygen as the ideal anæsthetic and that he gave a little ether as well, from ½ to 4 oz. The speaker looked forward to the day when nothing but gas and oxygen would be given except in rare cases.

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of this society on March 11th, Dr. H. S. Davidson, the President, took the chair, and a paper concerning the

Urinary Tract in Carcinoma of the Cervix

was communicated by Mr. Henry Wade and Mr. David Band. Two autopsy reports were given as illustrations of the end-results of extension of carcinoma of the cervix uteri so as to involve the urinary tract. In one the carcinoma had involved the bladder and one ureter. A vesicovaginal fistula was present, and involvement of the ureter had brought about atrophy of the kidney above. Death had been due to ascending infection and pyelonephritis in the remaining kidney. In the other case the neoplasm extended from the cervix and involved the ureter in the base of the broad ligament. Atrophy of the kidney had resulted. Death was brought about by involvement of the remaining ureter which led to renal suppression and anuria.

A fatal issue in carcinoma of the cervix uteri was frequently brought about by one of the following complications: (1) renal infection: (*a*) ascending pyelonephritis, (*b*) blood-borne pyelonephritis; and (2) renal suppression. As radium therapy had now superseded radical operation in the treatment of the majority of cases of cervical carcinoma, the information obtained from cystoscopy was now of considerable importance if the extent of the disease was to be accurately delineated. The effect of radium on healthy as well as neoplastic tissues made it essential that due attention be paid to the neighbouring organ, both as a guide to technique and dosage and for purposes of prognosis. Involvement of the bladder from anterior extension of carcinoma of the cervix might be recognised in six stages of increasing gravity: (1) elevation of the bladder floor; (2) fixation of the bladder floor, judged by digital manipulation of the cervix; (3) circulatory changes; (4) transverse ridge formation: (5) œdema; and (6) malignant invasion. Of these the first three appearances were those associated with any retrovesical collection or swelling, and as such might be produced by radiation of a cervical carcinoma, the bladder not being involved by malignant disease. In such cases the appearance of the ureteral orifice was very important as the earliest guide to the diagnosis of involvement of the lower urinary tract, and in a series of patients where spread of the cervical carcinoma was taking place the first changes in the bladder were noted there. The appearances of the ureteral orifice met with, in order of gravity, were fixation, retraction, circulatory changes, irregular gaping, and ulceration and nodule formation. In a series of cases in which such changes in the ureteral orifices gave early evidence of anterior extension of the carcinoma it was found that the general health of the patients remained excellent for over eight months before mechanical interference of the excretion of urine brought about renal incompetence.

By an operation such as intrasigmoid transplantation of the ureters complete vesical exclusion could be carried out safely, and after the operation the patient had comfort and complete urinary control. After successful transplantation, the lesion in the pelvis might be attacked with renewed hope, and irradiation or radical surgery might be directed entirely to the carcinoma and its eradication. Its efficacy need no longer be tempered by allowance for the protection or preservation of components of the urinary system.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY.

At a meeting of this Section on Feb. 27th, with Dr. J. Lait, the President, in the chair, a case of

Auto-agglutination of the Blood

was reported by Dr. William Boxwell. The patient, he said, was a woman aged 65, and in the winter of 1928 she developed jaundice while in France. When she was seen by Dr. Boxwell in July, 1929, all trace of jaundice had disappeared but she was anæmic. Attempts to perform blood counts or to prepare films of her blood failed owing to almost instantaneous agglutination of the red cells. She recovered and remained fairly well till July, 1930, when she was again examined. It then proved possible to estimate the number of white cells, although only with difficulty. They were found to be 40,000 per c.mm. and 86·5 per cent. of them were mononuclear leucocytes. A relapse occurred in August and the patient became very anæmic and jaundiced. Her hæmoglobin fell to 20 per cent. She was treated with liver extract, Ventriculin, and arsenic, and slowly improved; when she was seen in December last the red cells numbered 3,000,000 and white cells 6000 per c.mm. Hæmoglobin was 60 per cent.

Dr. J. W. Bigger described his investigation of the blood condition. Blood was collected in a warm syringe and divided into two portions, one of which was placed in a dry tube, the other in sodium citrate solution. Both were kept at body temperature and by centrifuging, surrounded by a water bath, the serum and cell fractions were separately obtained without chilling. The patient's cells were found, when tested against sera of the four groups, to act as normal Group O (Moss IV.) cells. The serum agglutinated rapidly and intensely all types of human cells including Group O cells and the patient's own cells. This, however, only occurred at air temperature and not at body temperature. When agglutinated cells were warmed to 37° C. they became uniformly suspended, and when again cooled they reagglutinated.

Dr. Bigger gave an account of the phenomenon of auto-hæmagglutination and distinguished it from pseudo-agglutination and pan-agglutination. He had, he said, found only 22 cases of true auto-hæmagglutination recorded. This case constituted the twenty-third and the first to be described in Ireland.

Dr. W. D. O'Kelly said he had tested very many sera for the Wassermann reaction, but had never encountered one which gave auto-agglutination.

Dr. R. A. Q. O'Meara read papers on (1) the mechanism of the Voges-Proskauer reaction, and (2) a method of detecting acetylmethylcarbinol formation by bacteria.—Dr. H. C. Drury described a case of thrombosis of the middle cerebral artery.

Hospitals and Approved Societies.—At the annual meeting of University College Hospital recently, when Prince George was elected President, Sir Herbert Samuel, the chairman, called attention to "the immense contribution which the voluntary hospitals are making towards the working of the National Health Insurance Act." Last year over 2000 members of approved societies were treated at a cost of £22,000, towards which the societies contributed only a little more than £3000. Of 124 of these societies whose members were admitted to the hospital 44 contributed part of the cost and 80 contributed nothing. The hospital is greatly in need of accommodation for paying patients. A beginning has been made by the provision of eight private wards in the Royal Ear Hospital, but further extensions are being delayed by lack of means.

REVIEWS AND NOTICES OF BOOKS

Diseases of the Chest.

By W. J. FENTON, M.D., F.R.C.P., Consulting Physician, Charing Cross Hospital; Physician, Hospital for Consumption and Diseases of the Chest, Brompton; and L. S. T. BURRELL, M.D., F.R.C.P., Physician, Royal Free Hospital and Brompton Hospital. London: Jonathan Cape, Ltd. 1930. Pp. 384. 15*s*.

THE writers of this book have had in view the requirements of the general practitioner and senior student and have endeavoured to make it as practical as possible. It has been written mainly from the clinical standpoint. They certainly deserve credit for having had the temerity to state in a text-book that the physical signs which formerly constituted the chief means of clinical investigation have acquired an importance somewhat out of proportion to their actual value in view of modern and more precise methods of diagnosis. The physician who has access to all the methods now available for the diagnosis of chest diseases knows that an X-ray examination must form an essential part of the proper examination of every chest case; he practises bronchoscopy and thoracoscopy and has learned the proper use and value of opaque oils in chest radiology. He does not need to be told how slender may be the connexion between physical signs and pathological facts. But the student beginning his clinical work is still taught to attach undue importance to slight variations in physical signs and may waste time in cultivating arts which have little practical bearing on the diagnosis of disease. The practitioner it is true cannot expect to master the complicated technique required for certain forms of investigation nor to be able to handle instruments whose safe use must depend upon specialised skill, but there is no reason why his attention should not be directed to the limitations of older methods and to the principles involved in the application of the new. He should at any rate be in a position to know when special methods are required and how to interpret the information obtained from them. Preliminary chapters give short accounts of the anatomy of the chest, the respiratory mechanism, and physical signs. The chronic and acute diseases of the lung are described in 20 chapters, illustrated by numerous well-selected radiograms. A further chapter deals with rare and unusual conditions. The inclusion of this is a good example of the common sense and mental balance that characterise the teaching of Dr. Burrell and Dr. Fenton. Nearly a third of the book is devoted to pulmonary tuberculosis.

The authors have endeavoured to compress a vast subject into a narrow space. On the whole they have succeeded, but their work might be improved by rearrangement in some places and by more explicit instructions for the guidance of the young practitioner in others. Thus in the chapter on acute lobar pneumonia, perhaps the most important one in the book, much of the treatment is given under the heading of Diet, while the section headed Treatment is fragmentary. The recently qualified student called to a case of pneumonia and wishing to refresh his memory by consulting this text-book might depart to his case having missed the best part of the teaching Dr. Fenton and Dr. Burrell are so well qualified to give him. The sections on bronchiectasis and new growths are particularly good. The only serious omission that we have noted is that of pulmonary asbestosis from the chapter on pneumoconiosis. The value of the book to the young practitioner would be still further increased by the substitution of prescriptions set out in full for the recommendations to use individual drugs.

Primary Syphilis in the Female.

By T. ANWYL DAVIES, M.D. Lond., Director of Whitechapel London County Council Clinic, and late Medical Officer in-charge Venereal Department, St. Thomas's Hospital. London: Humphrey Milford, Oxford University Press. 1931. Pp. 111. 12*s*. 6*d*.

THIS admirable work might well have a subtitle "And other lesions of the vulva and cervix," since Dr. Davies does not confine himself wholly to primary syphilis. The book is small, and every page is packed with information of the greatest value, based on personal observation. Primary syphilitic infection in women has not before, in this country at any rate, been subjected to detailed discussion, partly no doubt because facilities for intensive study and investigation have only been available for the past 12 years or so. Therefore there has been a tendency in text-books on venereal disease or on gynæcology to say that the primary syphilitic lesion is not frequently seen in women. Though from its relative painlessness, as well as from its more concealed position, the presence of a chancre is more often ignored by women than can ever be the case with men patients, this circumstance should not serve as an excuse for its being missed during clinical examination. Dr. Anwyl Davies has seen 578 cases of primary syphilis in women, and is in a position to draw conclusions as to relative frequency in the situation of chancres. His insistence on the cervix as the commonest site of primary syphilis in women should stimulate all who make pelvic examination to more accurate diagnosis of "cervical erosions."

Among the non-syphilitic lesions dealt with we would direct attention to Dr. Davies's page on condylomata acuminata, where he stresses the fact, not yet appreciated by some obstetricians, that in pregnancy this condition is frequently non-venereal. Trichomonas vaginitis as a cause of purulent vaginal discharge, sometimes associated with intolerable itching or with warts of the vulva, is also described. The bibliography is up to date and adequate, while the photographs and coloured plates demonstrate the clinical conditions in a helpful manner.

Das Ulcusproblem im Lichte moderner Röntgenforschung.

By Dr. H. U. ALBRECHT, Superintendent of the University Medical Clinic, Frankfurt A/M. Leipzig: Georg Thieme. 1930. Pp. 79. M.10.

MANY important questions in the nosology of ulceration of the upper intestinal tract are still matters of controversy. Even broad statistics, such as those of incidence and site; the relative incidence of gastric and duodenal ulcer; the sex-incidence and the season fluctuation, vary considerably according to the standpoint from which they have been investigated. Statistics compiled by a clinician are compromised by the uncertainty of his diagnosis; a surgeon only sees ulcers that come to operation, and the pathologist only those that come to post-mortem. Radiologists, on the other hand, are in a position to note all ulcers that give rise to clinical symptoms, and even to follow them through their course. A comprehensive statistical survey based on radiological findings has been made possible through the genius of workers—notably G. Forssell, H. H. Berg, and A. Akerlund—who have developed what they term the "relief study" of the intestinal mucosa; palpating with infinite care and thoroughness a small quantity of opaque food into all the folds. This method allows the diagnosis and location of an ulcer with much more precision than has hitherto been possible, though the quite recent innovation (see THE LANCET, 1931, p. 371) which enables actual photographs to be taken within the stomach should in competent hands provide results of comparable accuracy.

The work recorded in this book is partly a statistical study based on the investigation of 1527 cases, representing all the patients who complained of gastric disorder during two years at the clinic of Frankfurt University. It shows definitely that the incidence of ulceration is very much higher than has been supposed, the percentage of this large group with visible ulceration being nearly 24. The statistics will be of great interest to all workers who have realised the inadequacy of the present data. It is particularly interesting to compare these figures with those of the latest operation results published by D. C. Balfour from last year's work at the Mayo Clinic. The reproductions of radiograms, of which there are over 100, admirably illustrate the possibilities of the method. The work would be improved by a table of contents and an index, and also by a little more subdivision, but the reader in search of statistics will easily find what he needs.

Sixty Years of Health and Physick.

By S. G. BLAXLAND STUBBS and E. W. BLIGH. London: Sampson Low, Marston and Co., Ltd. 1931. Pp. 253. 15*s*.

THE authors here do not attempt to write an inclusive or categorical history of medicine; they point out that this has been done in several directions, and done very well, and throughout their work they give cordial acknowledgment to Dr. Charles Singer, Dr. F. H. Garrison, Mr. W. H. S. Jones, Sir Clifford Allbutt, and many others, who have helped to make the long story familiar to us. In this book it has been attempted, and with real success, to give a picture of the progress of ideas from primitive magic to modern therapeutics as that picture is reflected in the course of internal medicine, and the rapid survey ends with a note on the great accomplishments which have accompanied the development of medical theories, as they maintain their force, while the legitimate aspirations which may be founded upon the conquests of the past are passed in review. Recalling the dullness of the conventional school history, with its catalogue of king-names, the authors point out that they have discarded this method as far as possible, although certain names must inevitably stand out in the record. Their aim has been rather to seize upon the prevalent ideas of each age of medicine, fostered as they have been by the leaders at one epoch, and illustrate their fate as they were handed on, to be expanded, reformed, or perhaps discarded by the leaders in succeeding epochs; but where great names occur the ideas for which they stand are demonstrated, and sometimes set down in the words of the protagonists. In this way we have displayed to us a chain of succeeding intuitions with their deductions and sequences, and can see the interdependency of the links.

The book is delightfully illustrated, the pictures being selected always as aids to the telling of the story, which story shows two main things. First, it proves that while disease is far older than man the quest for health is far younger—it is an ironical fact that the earliest type of man known, the ape-like Java man (*Pithecanthropus erectus*), suffered from exostosis of the thigh bone which is very well shown in the plate. The second message of the book is that while medicine has none the less a long record of its own, it is only in recent times that our outlook has been revolutionised for the better by the assignment of the first place in our efforts to prevention. Sir Humphry Rolleston in a brief preface says: "In tracing the evolution of 'physick' from primitive magic to modern medicine the authors have successfully brought out the importance of the preventive idea which should permeate the teaching, practice, and research of the medicine of the future."

The first ten chapters and Chapter XIX. were written by Mr. Stubbs and the remainder by Mr. Bligh, the literary labours being shared almost exactly between them. They can also share in the credit which the book will undoubtedly bring them.

Indian Journal of Medical Research.

IN the current issue (Vol. XVIII., No. 3, January) J. A. Sinton continues his studies on malaria with special reference to treatment. In Part 14 he concludes that with a more prolonged course of treatment the permanent cure rate can be increased, but that the increase is not directly proportional to the duration of treatment or to the total amount of quinine given. The influence of the strain and virulence of the parasite in affecting cure is also considered. He concludes that seasonal effects are probably a factor influencing the mechanism of cure and relapse.—N. D. Kehar deals with aspects of the behaviour of cinchona alkaloids towards living cells, their penetration into colloidal gels receiving special consideration, as well as the effects of plasmoquine on the penetration of cinchona alkaloids.—H. N. Mukherjee and P. C. Gupta record a series of observations on the basal metabolism of Bengali Indians, and find that for young men the average is minus 13·3 per cent. (Aub and Dubois standards), a result possibly due to climatic and nutritional causes. Pulse pressure and vital capacity are also low.—K. K. Das contributes a note on the blood changes in filariasis, recording no marked fall in hæmoglobin percentage or in the red blood-cells from the normal standard.—Several papers deal with Indian sandflies. J. A. Sinton describes the diagnostic characters and differential diagnosis of *Phlebotomus eleanoræ* and *P. bailyi*, while H. E. Shortt adds a note on the feeding habits of *P. minutus*, stating that it never feeds on man in Assam. These results are at variance with a recent paper by R. B. Lloyd and L. E. Napier on the Blood-Meal of Sandflies, investigated by means of Precipitin Antisera.—A new species of culicoides is described by S. Mukerji.—Several papers by D. C. Wilson deal with osteomalacia and late rickets, while R. McCarrison records further observations on stone.—S. Sunder Rao figures a new species of human microfilaria to which he gives the name of *M. actoni*. The embryos were of very small size, devoid of a sheath and allied to *Acanthocheilonema perstans*. Unfortunately the description was made on a single blood smear, the case being later lost sight of.—S. M. K. Mallick and M. L. Ahuja consider the incidence of brucella agglutinins in an average unselected Indian population, healthy and febrile cases both being examined. Positive reactions were found distributed between the two groups. The volume contains divers other papers amongst which may be mentioned one dealing with the rat-flea survey of the Madras Presidency, and another with the cocaine habit in India.

THE LANCET.

LONDON: SATURDAY, APRIL 4, 1931.

CLINICAL USE OF OVARIAN AND PITUITARY HORMONES.

It is now some eight years since **Allen** and **Doisy** published their original communication on the preparation of the ovarian follicular hormone, œstrin. Many other investigators were soon at work along similar lines, and it was not long before an active water-soluble extract was obtained. Thus it may seem a little surprising that the substance has not yet attained a definite place in clinical medicine. During the first year or two after its appearance on the market enthusiastic reports of its action were indeed forthcoming, but later such accounts were not so frequent, and nowadays but few successful cases are recorded. A recent paper by A. S. **Parkes**[1] shows clearly why treatment of this kind is not at present likely to be satisfactory. Experimenting with baboons whose cyclical changes had been stopped by oöphorectomy, he was able by injection of œstrin to produce the vulval and peri-anal swelling which is characteristic of the follicular phase in these animals. But about 60,000–80,000 mouse units were required for this effect, and calculating on a basis of weight this would correspond to 400,000 units for an adult woman weighing 50 kg. Such large amounts have never been available, and it is therefore not to be wondered at that in clinical practice little has been achieved, except perhaps where ovarian deficiency is very slight. The present position is illustrated by three papers[2] lately published in this country. In the following table compiled from them the word positive indicates apparent response to the treatment and the dose is the total amount injected.

Number of Cases and Type.

—	Primary amenorrhœa.	Positive.	Secondary amenorrhœa.	Positive.	Dose range.
Shaw	5	0	8	6	—
Dodds and Robertson.	32	10	30	18	600–600 rat units.
Gardiner-Hill and Forest Smith ..	7	1	37	20	30–500 rat units.

The cases chosen were for the most part those in which it appeared that the fault consisted in ovarian deficiency only. Where this was primary the results were not strikingly successful; where it was secondary they were more encouraging. The range of dosage available was, of course, small in comparison with the very large figure mentioned above.

The figure of 400,000 mouse units is the dose for subcutaneous injection, and if the œstrin were to be given by mouth an increase of at least ten times would be needed, making 4,000,000 in all. The exact relation between subcutaneous and oral dosage of œstrin is not, however, decided. E. **Laqueur** and co-workers in 1927 found that 100 times the subcutaneous dose was necessary to produce œstrus when it was given by mouth, but some of the German workers find that its oral efficacy depends on the activity of the preparation; for example, with one containing 8 million units to the gramme, 50 units are required to produce œstrus, whereas with one containing 200,000 units to the gramme only 6 units are required. M. M. **Maino**[3] lays stress on the importance of the vehicle used in administering the hormone. With an alcoholic solution, he says, the oral and subcutaneous doses were identical, and this is a result whose comfirmation will be awaited with interest. It is clear, however, that whether the oral dose is or is not equal to the subcutaneous dose, the quantity needed for human beings is so great that there is no immediate prospect of a sufficient supply being available and cheap enough to make œstrin medication generally practicable.

As regards the anterior pituitary or placental hormones there is only one field in which incontrovertible results have been obtained in clinical practice—namely, the Aschheim-Zondek test for pregnancy. Owing to the definiteness of the results the interest centred at first on the ovaries, and it is only latterly that the influence of these hormones on the male genitals has been studied. Most workers agree that the most striking effect of anterior pituitary treatment in the immature male is a stimulation of the growth of the seminal vesicles and prostate; the testes appear to be relatively little affected, at any rate as far as gross weight is concerned. In the female the anterior pituitary hormones act on the uterus and vagina through the ovary, and in an analogous way they act in the male through the testis, so that after castration they have no effect on the vesicles and prostate. Their action on the testis does not seem, however, to have been fully worked out. Some workers assert that these actually decrease in weight as a result of anterior pituitary treatment. Histologically the interstitial tissue is found to have undergone hypertrophy; in some parts the spermatic elements have suffered damage, in others no evidence of damage is seen and there may even be signs of partial stimulation, consisting in an increased production of spermatocytes, without an increased or premature production of spermatozoa.

Further information on the action of hormones obtained from the urine of pregnancy is contained in a series of papers recently appearing in the *Münchener medizinische Wochenschrift.* The third of these (Jan. 2nd, p. 19) deals with the influence of the follicle-ripening fraction (prolan A) upon the genitals of immature rats. In the male no stimulation of interstitial tissue was observed, and corresponding to this there was no growth of seminal vesicles or prostate. Using the unsplit prolan A-prolan B mixture a much greater degree of damage to the spermatic elements was noted, but the interstitial tissue was markedly hypertrophied; in this case the accessory organs were enlarged. It is interesting thus to note that the follicle-ripening hormone is, in the male, capable of bringing about a certain degree of maturation of spermatozoa, but appears to be unable to complete the process. This result was indeed reported in 1927 by Smith and Engle[4] who found that while the interstitial tissue is hypertrophied, spermatogenesis is not accelerated and there is sometimes actual damage to the spermatic elements. In the adult rat, however, B. P. Wiesner[5] was able to obtain renewal of spermatogenesis after this had almost ceased. There is therefore some other factor (or factors) concerned in the production of ripe spermatozoa which does not seem to arise in the anterior pituitary, or to be present in the urine of pregnancy. While it may appear that there is some foundation for a rejuvenation technique in the male by the use of anterior pituitary products, our knowledge is so narrow that at present their clinical use must be regarded as little more than guess-work.

A TUBERCULISED COMMUNITY.

Visitors to health resorts in the Alps where tuberculous patients foregather have often felt qualms about the risk of sojourning in such a community. Opinions have varied from the vague statement that Davos is a hotbed of infection to the categoric assurance that no death from tuberculosis has ever occurred in any native of the valley. The local medical fraternity has generally been content with the placebo that whatever may be the risk of infection it is more than balanced by the immunity provided by the environment. Exact figures have been hard to come by, but we now have a remarkable study[6] of the tuberculisation of a well-known Alpine station by a medical man with a peculiarly intimate knowledge of the facts; for as pastor in the valley he was acquainted with the domestic life of the inhabitants, and after taking his medical degree he practised as school doctor. As Arosa is his field of investigation it may be wise at once to anticipate his conclusions by stating that, although evidence of tuberculisation is unquestionable, there has been nevertheless a death-rate from tuberculosis among the inhabitants scarcely one-half of that in other parts of Switzerland. The development of Arosa as a health resort makes any statistical analysis difficult. In 1850 it was an isolated village with a diminishing population, then numbering at most 75. In 1884 came the first winter visitor. In 1888, when there were 88 inhabitants, appeared the first publication of its value as a health resort. In 1893 occurred the first death from tuberculosis in a native. In 1900 there were 1071 inhabitants, and the first disinfection order was issued. In 1910 the number of winter visitors first exceeded 1000, in 1929 they numbered 3200, of whom one-half were there for winter sport. The inhabitants had then increased to 2931.

Dr. Gahwyler set himself to determine the tuberculisation by examining all the school-children by Moro's innunction test. This he was unable to do until the autumn of 1929, as up till then one of his colleagues had expressed a doubt of the harmlessness of the test. As a matter of fact in the case of four children of 7–8 years there was a complaint of fever and loss of appetite, possibly associated with the test. Only six parents of the 233 children of all ages in the school refused to have their children tested; six children had been at school less than a year and were not included. Of the remaining 221, 139 reacted, giving a percentage of 62·9 reactors; 55·5 per cent. reacted already in their seventh year, compared with 20 per cent. for Zurich school-children of the same age. No such high figures are on record elsewhere; those of Kiel approach most nearly. Analysing the results in three groups Dr. Gahwyler found more positive results among those born in Arosa than immigrants. Two-thirds of the positives came from relatively well-to-do families. Tuberculisation was twice as intense in the centre of the village as in the periphery. Children of the same family were in general all reactors, but there was an instructive case of five older children born while their parents were keeping a small pension who were positive, while a sixth child born after the parents were managing an hotel in which they had separate quarters was negative at 5 years of age. In another family all the older children were infected by an aunt; the youngest child born after her departure remained Moro-negative. In all these children clinical examination showed nothing unusual. About a quarter had enlarged glands, but a number of them were non-reactors. X ray examination revealed no single case which Dr. Gahwyler could interpret as early tuberculous infiltration; all the shadows indicated infection which had taken place in the pre-school years. It is worthy of note that of all these children only two showed any signs of rickets and these had not spent their early years in Arosa.

Turning to the actual illness produced by this frequent tuberculisation of the local children, Dr. Gahwyler found most surprisingly that it accounted for little or no school absence. On the average at most one of the 200 school-children was absent during the year from any tuberculous disease; at the present time it is a 13-year old girl with coxitis. Thus the morbidity in school age is practically nil. Nor could he find any school leaver who sickened with active tuberculosis in Arosa during the dangerous years from 15 to 25;

[5] Edin. Med. Jour., 1929, xxxvii., 18.

[6] Gahwyler, M.: Tuberkulosedurchseuchung, Morbidität und Mortilität in Arosa, 1890–1929, Beitr. z. Klin. der Tub., 1930, lxxv., 269.

a single 18-year old girl was reported to have severe phthisis after going to live in Milan. On the other hand in the pre-school age the morbidity was definite. Between 1916 to 1925 he saw 7 children under 5 years of age with tuberculous pneumonia, 12 with persistent bronchial gland inflammation, 2 with primary lung infiltration, and 1 each with otitis, keratitis, and cervical lymphoma. All these children are to-day quite well. It strikes Dr. GAHWYLER, as it will strike others, as remarkable that in spite of daily contact in the restricted space of a small boarding-house, often at the same table with cases of open tuberculosis, no single school-child became seriously ill. Good climate in itself can hardly account for this immunity. Possibly, he suggests, the high hæmoglobin value may produce an individual immunity so that daily superinfection acts like a course of therapeutic tuberculin. The immunity may be further due to the intensive insolation, especially with ultra-violet rays, for in Arosa the school-children do not live the usual indoor winter life of the lowlands. The bodily hardening which certainly does not shield from infection seems to raise the level of the immunising forces after infection has occurred.

Finally Dr. GAHWYLER comes to the mortality from tuberculosis among the children of those who were born or have settled permanently in Arosa. Before the valley became a health resort no native died of tubercle, but then of course there were few of them to die. In 1893 occurred the first death, being that of a 14-year old peasant girl who did a patient's room in a neighbouring house. All the other 19 deaths in the 40 years 1890–1929 occurred in the families of those who settled in Arosa on account of tuberculous disease, although a certain number of deaths may also have occurred among those who married into the valley or worked there temporarily. For instance, three fatal cases occurred at a laundry. Of all these cases no single one died of chronic phthisis. Death was always the result of the primary infection or of the secondary stage of generalisation. Actually the deaths were certified as meningitis 11,; tuberculous pneumonia, 5; renal tuberculosis, 2; pulmonary tuberculosis, 2. Five of the deaths were under one year, five from 2–5, five from 5–15, and five from 15–30. Stated as a proportion of the total number of settlers the result is 7·1 deaths from tuberculosis per 10,000 living, as compared with a figure of 13·8 for Switzerland as a whole. This, as Dr. GAHWYLER remarks, is the more striking as Arosa has no tuberculosis dispensary; doubtless every doctor makes it his duty to call attention to the dangers of infection, and the official school examination must have a similar educational effect. Of the nature of the infection when it occurs, Dr. GAHWYLER thinks we can no longer be sure. The seven intra-familial fatal cases he attributes to a superinfection occurring in the anergic phase of the primary stage. In other infections within and without the house the child has generally had time to develop its own immunity and allergy. Constitution plays the same rôle as in the plains, and Dr. GAHWYLER emphasises again the fact that even the smallest child is exposed to fresh cold air for hours a day throughout the winter and thus lays up a store of health for the rest of life.

THE OSTEOPATHY BILL.

THE full text of the Registration and Regulation of Osteopathy Bill is now available; it will doubtless receive the careful attention of the medical profession. The "practice of osteopathy" is defined to "include the performance of any such operation and the giving of any such treatment, advice, or attendance as is commonly given by osteopaths and any other necessary measures required for the efficient performance of osteopathy." To decide what treatment is "commonly given by osteopaths" may be a matter of considerable controversy. If the proposed definition were to become law, it would seem that, provided that persons calling themselves osteopaths make a sufficiently vigorous invasion of the province of the surgeon and the medical practitioner, there is no form of surgical operation or medical treatment which will not be part of the practice of osteopathy. Clause 7 gives the registered osteopath most of the scanty privileges at present reserved for registered medical practitioners. Though the Bill apparently concedes no direct authorisation to prescribe and use drugs which come under the Dangerous Drugs Acts, it proposes to empower the registered osteopath to sue for his fees in a court of law, notwithstanding the existing restrictions in Section 32 of the Medical Act. The Bill further proposes to allow him "to sign certificates of birth and certify the cause of death and sign certificates of death, and, provided he is licensed as hereinafter provided, to administer anæsthetics and perform minor operations." In spite of the qualification that the operations are to be minor operations, and in spite of an imposing list of subjects and minimum hours of study therein scheduled to the Bill. Clause 7 seems to contemplate a remarkable range of practice for the osteopath, and a remarkable confidence in his powers of diagnosis. Not only is his position in the matters already mentioned to be thus equalised with that of the registered medical practitioner; in one respect it is to be made far superior. Under Clause 8 the registered osteopath is given a monopoly of practice in terms resembling those of Section 1 of the Dentists Act of 1921. At present, as registered medical practitioners know to their cost, persons who have duly qualified in the practice of medicine and surgery have no legal protection whatever against the invasion of such practice by the unqualified. If the new Bill were to pass into law, it would seem possible that duly qualified surgeons, while themselves having no monopoly as against the osteopathic invader, might actually be restricted in their use of certain forms of manipulative treatment because of the monopoly to be conferred upon osteopaths. The remaining clauses of the Bill have affinities with the legislation affecting medical practitioners, dentists, and veterinary surgeons. There is to be

Where the secreting power of the kidney is damaged, the faintness or absence of the shadow produced by the excretory method gives an index of the degree of injury to the concentrating power of the kidney. There are other cases in which instrumental urography may fail, either wholly or in part, and in which the excretory method furnishes good visualisation. In tuberculosis, for example, the presence of cystitis often precludes the use of the instrumental method, while excretion urography can be used with safety. Physiological disturbances such as atony of the ureter following obstruction or infection, and anatomical variations such as ureteric kinking or fixation are shown by excretion with a certainty which the instrumental method cannot achieve. It is possible, moreover, to determine by excretion urography whether a much distended ureter is capable of emptying itself actively or not. Such an opportunity for the estimation of physiological function may have a bearing on the choice between conservative and extensive operations. In some cases—for example, where the ureter is occluded by stone or new growth—the instrumental approach to the kidney cannot be employed but excretion urography often gives a clear picture. Prof. Lichtenberg bases his conclusions on observation of more than 2000 cases, and his radiograms show the high degree of definition to be obtained by the use of the new contrast substances.

ANASTOMOSIS OF NERVES.

It is just over a hundred years since Flourens divided the two main nerves of the brachial plexus in the cock and united the central end of one with the peripheral end of the other, showing that the communication of impulses was perfectly re-established and crossed. Sir Charles Ballance has recently published[1] an account of some experiments in which the central end of the cervical sympathetic nerve was anastomosed to the peripheral end of the facial nerve or hypoglossal nerve. His work was therefore the reverse of Langley's. The sympathetic-facial anastomosis was done on six cats, two monkeys, and two dogs. Six months later the muscles of the face had recovered voluntary movement and responded to faradic stimulation, but when the sympathetic was exposed in the lower part of the neck the muscles of the face did not contract. When the anastomosis or the sympathetic proximal to it was stimulated, they did contract. It seemed possible that in some instances nerve-fibres had reunited the divided ends of the facial nerve. This certainly did not occur in all the experiments; the predisposing factor was shortness of the trunk of the facial nerve. The failure of the faradic current to cause contraction when applied to the lower part of the sympathetic in the neck seemed to be due to the scar tissue which inevitably forms under the sterno-mastoid after the operation. Through this mass of scar tissue the impulse fails to pass, though a normal impulse originating in the central nervous system may succeed in getting through. In a typical experiment on the cat the first results are enophthalmos, small pupil, dribbling of saliva, and a flaccid paralysed face. After three months the face is symmetrical and the neuro-muscular mechanism is restored sufficiently to give reflex response to stroking the bristles. After four months there is no deformity at rest, but some inequality is visible when the animal eats. All the muscles respond well to faradic stimulation. In seven months recovery appears to be complete. When the sympathetic was joined to the hypoglossal in a cat and the animal examined three months after the operation, the operated half of the tongue was thinner and narrower than the other half and required a stronger faradic stimulation for response. In six months' time the two halves were equal and moved together; when the sympathetic was stimulated in the lower part of the neck, on the side of the anastomosis, a ripple of contraction passed along the tongue on that side. The usual signs of division of the cervical sympathetic persisted. There was much less scar tissue in this operation than in the other, and no reunion took place in the hypoglossal nerve. In another experiment the cervical sympathetic was joined to the descendens hypoglossi when the sterno-thyroid and sterno-hyoid recovered.

These experiments seem to show definitely that the cervical sympathetic nerve is able to carry impulses to nerve-endings in striated muscle. The essential element in the neuro-muscular mechanism is not a particular group of fibres, but the central cells and the nerve-endings, and the route by which the impulses travel from one to the other is immaterial. Sir Charles Ballance thinks that on the whole his work supports the view that the anatomical and functional perfection of striated muscle depends on a dual innervation.

CHOLESTEROL AS PRO-VITAMIN A.

CAROTENE as the parent substance of vitamin A has received considerable attention, and as we pointed out last week the authenticity of the relationship has become increasingly probable. The claim by H. Seel and F. Dannmeyer that cholesterol can be the direct precursor of the vitamin nevertheless deserves consideration. The suggestion is not a new one. The possibility was examined several years ago by O. Rosenheim,[1] who noticed that the substance or mixture of substances (oxycholesterol of Lifschütz) which is produced when cholesterol is oxidised gives the blue colour with arsenic trichloride reagent, which is characteristic of vitamin A. For various reasons Rosenheim abandoned the idea that oxycholesterol is, or contains, vitamin A. The blue pigment did not appear to be truly identical with that yielded by cod-liver oil; and when oxycholesterol was dissolved in natural animal or vegetable fats, the production of the blue colour reaction was totally inhibited, a peculiarity which appeared to establish a different identity for the two chromogenic substances. Some biological experiments were made with Rosenheim's material; the results were not entirely conclusive, but were deemed to be against the view that it possessed the properties of vitamin A. Other workers have obtained a similar negative result; the only positive finding indeed is that of Seel, a full account of whose work with Dannmeyer, including a description of the animal experiments, is set out in two papers in Schmiedeberg's *Archiv für Experimentelle Pathologie und Pharmakologie*.[2] In the earlier of these two papers a number of products of cholesterol and of sitosterol, both before and after their irradiation with ultra-violet light, were examined on rats for their power to prevent rickets (vitamin D) and xerophthalmia (vitamin A). These substances included cholesterol, cholesterol oxide, oxycholesterol, sitosterol, oxysitosterol, and a number of others. Of these only the oxycholesterol, both before and after irradiation, prevented xerophthalmia, and only the cholesterol and oxycholesterol after irradiation prevented rickets. It is to be noted that the capacity to prevent or cure xerophthalmia is taken as the criterion of activity in vitamin A; very little evidence is adduced as to the presence of the growth-promoting function, a point which may be significant. In the first series of experiments, the materials were in ethereal solution, which was dropped upon the diet of the rats, in measured amount, and the ether allowed to evaporate. In the second paper, further experiments with oxycholesterol are described and also some comparative ones with a concentrate of the unsaponifiable fraction of shark (piked dog-fish) liver oil. The shark liver oil concentrate was potent in doses as small as 0·00001 mg., while the oxycholesterol was not active in a dose below 0·01 mg., suggesting that the latter is a mixture of substances, of which the active part forms only a small fraction. A specimen of oxycholesterol, which was sent by Lifschütz, had an even lower biological value and only gave the antimony trichloride reaction very weakly.

[2] Seel, H.: Arch. f. Exp. Path. u. Pharm., 1928, cxxxiii., 129; 1931, clix., 93.

In this series of experiments the oxycholesterol was dissolved in olive oil for administration to the animals; in this solvent, in direct contrast with Rosenheim's results, the blue colour reaction was produced and was not fugitive. Dissolved in cod-liver oil oxycholesterol gave a blue colour reaction, which was fugitive like that of the vitamin A native in the cod-liver oil. Seel attributes the impermanence of the blue colour, when produced in cod-liver oil, to some constituent of that oil, for he found that the more he purified vitamin A from other liver oil constituents the more permanent the colour became. The permanence or impermanence of the blue colour produced by the antimony trichloride reaction he regards therefore as not characteristic of the chromogenic substance but as depending rather on the solvent medium. The spectroscopic examination of oxycholesterol was said to show the absorption band at 327 $\mu\mu$ in the ultra-violet, which is regarded as characteristic of vitamin A; but the absorption spectrum in the visible part of the spectrum of the blue product of the antimony trichloride reaction is not described, so that the presence or absence of the characteristic absorption band at 610 $\mu\mu$ is not established. Seel believes with Takahashi that the vitamin A formed on oxidising cholesterol is of a sterol nature, and that it is a very labile partial oxidation product of cholesterol. It would appear not impossible for vitamin A to be derivable both from a sterol and from carotene, but until this very interesting contribution has been fully confirmed further discussion of its implications can only be conjecture.

ACCOUNTS OF AVERTIN FATALITIES.

It is notoriously difficult to arrive at a true estimate of the death-rate for any one given anæsthetic. The factors which play a part in the fatality are usually many, and their relative importance is often hard to determine. Moreover, adventitious circumstances influence individual judgment so differently that even the death itself is variously interpreted; one man will call it an "anæsthetic death" where another would refuse to do so. Consequently we can place little value, generally speaking, on statistical inquiries into so-called anæsthetic deaths. The justification for this mental reservation we do not find shaken by Oscar Schuberth's recent investigation of the literature of deaths caused by avertin narcosis.[1] He has collected accounts, some of them meagre to the point of uselessness, of 72 so-called avertin deaths. After examining the details he comes to the conclusion that "most cases mentioned as avertin deaths will thus, on critical examination, be found not to admit of such a classification. If the great number of avertin narcoses performed is taken into consideration the published cases of death are not more numerous than would justify a continued use of this narcotic." Schuberth does not make any attempt to estimate the number of avertin administrations, of which the 72 cases might give a proportional death-rate. He decides that of these 72, 11 were, with certainty, real avertin deaths, and 3 others probably so. In the others avertin is not regarded as the responsible factor.

DR. OLIVER GOLDSMITH.

Oliver Goldsmith, like Keats and Smollett, is known as a qualified doctor, but of the famous trio Smollett was the only one who ever practised his profession, and, it seems, the only one about whose actual qualifications there is no doubt. Goldsmith has been reported to have failed to obtain a licence at Surgeons Hall, but there is some evidence now that he was M.D. Oxford ad eundem gradum. This fact has escaped the University records, but Sir William Osler discovered in a newspaper of the particular year, 1769, a note on the granting of the degree. An ad eundem degree is only conferred on those who already hold the same degree in a comparable university, and the note went on to state that Goldsmith was the recipient of a medical degree from Trinity College, Dublin. This fact also goes without substantiation from the University, but it appears from other evidence that the degree was granted in absentiâ, possibly for medical work done on the continent. So it seems that Goldsmith may have been a qualified doctor, but his short attempts to exercise his profession were unsuccessful.

A sketch of his life reaches us in the form of a communication made by Dr. J. N. Elliott Brown, of Toronto, to a local scientific society, in which the known facts are resumed and others are set out which will be novel to most readers. These make a vivid and attractive picture of a brilliant wayward man. Born of a gentle and absolutely improvident family, Goldsmith received a desultory education at Dublin University, learned French from some Catholic priests whose acquaintance he made casually, and finally presented himself before a bishop to be examined for Holy Orders. He failed to satisfy the prelate of his suitability for the office of clergyman, and decided to enter the profession of law, having found here a financial backer in the person of a good-natured uncle Contarine. This again proved a false start, at which point he became a medical student in Edinburgh. Dr. Brown supplies interesting notes on the careers and characters of the Edinburgh savants, and tells in detail the story of Goldsmith's celebrated European tramp which lasted a year, and which, according to the traveller, included Leyden, Paris, Berne, Geneva, Milan, Florence, Venice, and Padua. "Goldsmith left Leyden on foot with a guinea," says Dr. Brown, "which he had borrowed, a shirt and a flute. His final objective was Padua, where the great Morgagni reigned supreme in the Italian medical world. It took Goldsmith ten months to reach his goal. Before starting he noticed some rare tulip bulbs in a shop, and recalling his good uncle Contarine's love of flowers, bought a supply of the bulbs and forwarded them to him." How many of the galaxy of eighteenth century physicians, physicists, and philosophers, who might have been met in such a wander-jahr, Goldsmith personally encountered is doubtful—certainly not all those whom he professed to have spoken with—but he seems to have included medical among his other experiences, even if his statement be not accepted that he received a medical degree at Padua.

---

[1] Acta Chir. Scand., 1931, lxviii., 55.

Dr. Brown describes a man, brilliant with tongue and pen, charming, humane, and learned, who possessed no characteristics that would make it likely that he would succeed in the practice of medicine and many that would have antagonised his professional chances.

STREPTOCOCCAL INFECTION THROUGH MILK.

THE cow is in some ways imperfectly fitted for her high calling. Her mammary glands are situated so far back that constant care is needed to keep them clean; she shares with mankind a number of important constitutional diseases such as tubercle; and occasionally she acts as intermediary in the spread of human infections from one person to many. This last possibility—of the cow acting as a local vehicle for infection—is not nearly so well recognised as her other defects, but is well worth consideration, especially as it concerns the streptococci. In the 'eighties much interest was aroused by Power's suggestion, fortified by Klein's investigations, that the human outbreak of scarlet fever at Hendon was due to scarlet fever in the cow. This conception was repudiated by the veterinary profession and fell into disrepute and almost derision. On the other hand, between 1890 and 1910 a number of outbreaks of human sore-throat were reported which were undoubtedly spread by milk and which were often associated with a cow suffering from mastitis, whose removal from the herd stopped the outbreak. The puzzle was that bovine mastitis was very common while these outbreaks were distinctly rare. Investigating the problem for the Local Government Board in 1906–09, W. G. Savage satisfied himself that the ordinary type of bovine mastitis was harmless to man but that the bovine type of streptococcus was not the only streptococcus responsible. From these experiments, aided by the known fact that rarely implantations of diphtheria bacilli occur on teats of cows, he advanced, in 1911, the view that while the ordinary bovine mastitis and teat lesions were harmless to man, occasionally there is a local infection with organisms of human origin. In such cases these human strains of streptococci may be decidedly prejudicial to man. Applying the same hypothesis to scarlet fever, and after a study of the original records, he considered the Hendon outbreak as not due to a constitutional disease, bovine scarlet fever, but due to a local infection of the cow with the organism of scarlet fever.

Subsequent extensive work, mainly in America, has shown that this hypothesis is almost certainly true for angina outbreaks and is probably applicable to some milk-borne epidemics of scarlet fever. Bacteriologists in America and in England have devised valuable tests to distinguish between streptococci of bovine type and those of human ancestry found in a bovine habitat. While these identification tests make it possible to ascribe with some precision the origin of a milk-borne outbreak due to streptococci, they have brought to light some points of difficulty. For example, American workers—and now Minett and Stableforth in this country—have been able to identify the human pathogenic types of streptococci in the udders of certain cows without this fact being associated with human disease. At a discussion reported on p. 755 of this issue various possible explanations were suggested but none is as yet supported by convincing evidence. We also do not know the conditions under which these human types of streptococci infect the udder, but there is some evidence that teat or udder injury is an important factor.

On the epidemiological side there are also unsolved problems. After about 1910 sore-throat outbreaks spread by milk stopped, or were not recorded, in Great Britain until the Hove outbreak in 1929. On the other hand, they were not recorded in U.S.A. until 1911, and have continued to be reported there up to the present time. We have no reliable data capable of explaining this curious distribution. Whatever may be the explanation it is interesting that the cow can under certain circumstances take to its bosom human streptococci possessed of pathogenic properties, and allow them to multiply and infect the milk in vast numbers. In Hove and Brighton there were over a thousand cases and more than sixty deaths.

GLASGOW OBSTETRIC CONGRESS.

THE eighth British Congress of Obstetrics and Gynæcology will be held by invitation of the Glasgow Obstetrical and Gynæcological Society in the Lister Memorial Lecture Hall of the Royal Infirmary, Glasgow, from Wednesday, April 22nd, to Friday, 24th. The Congress is organised by three English, two Scottish, and two Irish societies; on this occasion Dr. David Shannon will preside. The first day will be used to discuss the clinical and pathological features of ovarian tumours (excluding endometriomata), to be introduced by Prof. Blair Bell and Prof. Beckwith Whitehouse from the clinical side and Mr. T. G. Stevens from the pathological side. On Thursday morning Prof. S. A. Gammeltoft, of Copenhagen, will open the session with a paper on the teaching of obstetrics and gynæcology in Denmark, and Prof. H. Guggisberg, of Berne, will open the afternoon session (at the Anatomical Institute) by a paper on the conditions of life and reproduction; later Prof. T. H. Bryce will demonstrate the famous Hunterian collection in this institute. Friday afternoon will be devoted to visiting various hospitals in the city. There will be numerous individual contributions to the various sessions, and Dr. Alice J. Marshall is in charge of a special museum of pathological specimens. On the social side, members of the Congress will be received by the President and Mrs. Shannon at the College Club on Wednesday evening, and members will dine together at the Central Hotel on Thursday. On Saturday will be unveiled in the cemetery of St. Kentigern at Lanark the renovated tomb of Dr. William Smellie. The secretaries of the Congress are Prof. James Hendry, 7, Clairmont-gardens, Glasgow, C. 3, and Dr. John Hewitt, 16, Whitehill-street, Glasgow, E. 1.

AT a meeting of the Royal College of Physicians of London on March 30th, Lord Dawson of Penn was elected President in succession to Sir John Rose Bradford.

FISHING RIGHTS FOR HOSPITALS.—Mr. G. M. Leman, a retired schoolmaster residing at Kirkbythore, has presented to Cumberland Infirmary and Penrith Cottage Hospital, in equal shares, 28 acres of land on the River Eden together, with the appurtenant fishing rights. The land is situated on the Bolton side just opposite Kirkbythore. Mr. Leman has at the same time given £50 to Penrith Hospital.

THE PROBLEM OF THE MILK-SUPPLY.

REVISION OF DESIGNATIONS.

By VISCOUNT ASTOR.

I RECENTLY initiated a debate in the House of Lords on the milk-supply during the course of which Lord Moynihan pointed to the injury caused by tuberculous and contaminated milk. Every surgeon could probably confirm this and give similar illustrations. But the misunderstanding created by his speech in agricultural circles shows how little that industry is ready to acknowledge the risks, and *therefore prepared to put matters right*. On the other hand, the difficulties of farmers and of legislators and administrators may not be realised in medical circles. As we need an instructed public opinion before we can get progress I propose to outline certain aspects of the problem which have not been fully dealt with in the articles and letters recently published in THE LANCET, and to put forward suggestions for improving matters.

WOEFUL UNDER-CONSUMPTION.

Let me begin by summarising certain facts which are beyond dispute. In England there is a woeful under-consumption of liquid milk. Canadians drink twice as much per head, Americans thrice, Danes and Swedes *six times* as much as we do. There are whole streets in some of our industrial cities where not a drop of milk is purchased. Much of the surgical tuberculosis is of bovine origin. Much infantile diarrhœa in hot weather is attributable to stale, decomposing dirty milk. The dairy industry suffers considerable financial losses through premature souring. All of this is so in spite of a genuine improvement.

The imports of dairy products are increasing so that they are worth (1928) £72,433,198, and represent the output of some 130,000 cows, whilst the imports of dried and condensed milk alone represent the output of about 50,000 cows and are worth £5,500,000 to overseas producers. Yet farmers complain of a glutted milk market. *There obviously cannot be an* over-production when there is such an under-consumption of milk.

And all the time we know that milk is an essential food for children, and we ought to realise that at present prices it is a cheap food. One quart of milk costs 7*d.*, whilst the following equivalents in food value to a quart of milk cost more—i.e., one pound of lean meat 1*s.* 2*d.*, 10 eggs 1*s.* 8*d.*, 2 lb. of cod fish 2*s.*, 1 lb. of chicken 2*s.* 6*d.* The experiments of Dr. H. C. Corry Mann and Dr. J. B. Orr prove that if school-children are given a daily ration of milk in addition to their usual meals, their height, weight, health, spirits, and ability to use their brains increase. Such a ration would mean a new market for milk producers worth £4,000,000. Even if provided free by the taxpayers it would cost £2,000,000 less than last year's sugar-beet subsidy and be of far greater benefit both to agriculture and to the nation.

Dairying and livestock should be made the corner-stones of British agriculture. We have the right climate, and are pre-eminent in livestock. Cows are found all over the country and are not restricted to particular districts like wheat, sugar-beet, or hops. They are associated with all types of farming—small and large, grass and arable. Our dairy produce as sold off farms (1928–29) is estimated at £56,000,000, our livestock at £78,600,000. This is far more valuable than our wheat crop (£12,000,000), to stimulate which certain political and agricultural leaders contemplate asking the overburdened taxpayer for a subsidy of £5,000,000 to £10,000,000.

A CHAOTIC SITUATION.

The milk situation is chaotic, muddled, unsatisfactory both for agriculture and for the welfare of the nation, particularly its children.

National interests require that we should at least double our consumption of home produced liquid milk and reduce our imports. But national interest equally demands that our supply should be far safer *than it is to-day*.

No "government" (used in its widest sense) could back a "*Drink more milk*" publicity campaign, no Government could urge education authorities to get school-children drinking milk unless at the same time a guarantee could be given that the milk was reasonably safe. To-day such a general assurance could not be given.

In the past—and to-day still—farmers have refused to admit the facts of the situation. Farmers are too apt to take up a short-sighted attitude. "Leave us alone, don't stir up discussion about milk," is often their cry. If the dairy industry were flourishing, if we were drinking as much milk as other nations, this attitude might be justifiable. But it is hopelessly unbusinesslike to-day when milk imports are rising and home sales are low. In 1914 in the House of Commons I made the then novel suggestion that milk should be graded and labelled according to its hygienic quality. The agricultural M.P.'s as well as Ministers representing the Local Government Board and Board of Agriculture fell on me as a heretic and Philistine, insisting that there must be only one quality and that the best. The result, of course, was that for years there was only one quality, and that the worst. Gradually we have become more enlightened and for some years now grading according to cleanliness has been recognised. The bacterial content and the tuberculin test are at last admitted to be as important as butter-fat content.

THREEFOLD REMEDY.

What, then, are the obstacles? What is wrong? and above all, what is required of the milk trade, of the legislature, of our administrators (national and local) to put things right?

Three things are needed. Firstly, a better milk supply; secondly, publicity; and thirdly, cheap milk. Adequate propaganda is impossible until the commodity advertised is reasonably safe or at least until the public know which of the milks offered is safe and which is not safe. The price of milk can be reduced or if (as is possible) the steps taken to improve the supply add to the cost then this reduction of cost (which must take time) should keep the price steady. Anyway I will not enlarge upon the steps required as they are mainly concerned with the industry itself. They include more up-to-date methods of feeding, management of land, of livestock, &c. The Ministry of Agriculture might also help considerably by providing free tuberculin testing for farmers who desired to rid their herds of reactors. The whole question of testing might be clarified and improved. Owners of herds often complain that many veterinary surgeons were trained before the modern technique connected with this test was taught. They know also that the tuberculin on the market is not standardised and that as a result of all this tests are on occasions unreliable.

But there is one aspect which I do desire to examine in detail in this article, one in which readers of THE LANCET can help to educate opinion and help to get a move on. THE LANCET of Dec. 13th, 1930, published a letter signed by Lord Dawson of Penn, Sir Thomas Horder, and other distinguished men. In that letter it was stated that there was "a certain measure of confusion arising from the excessive number of grades." On March 7th, 1931, THE LANCET published a most instructive article by Dr. W. G. Savage, M.O.H. of Somerset, in which he stated that in its practical operation the Milk and Dairies Order in rural districts was largely a dead letter; that much milk was heat-treated with no health objective, but as a trade practice; that there was no obligation to disclose the fact that milk had been heated; and that some milk was actually heated more than once before sale.

Until the public (including medical men) know by the label it carries what the hygienic quality of any sample of milk offered for sale is we shall not get that increased consumption which is desirable in the interest of children, of adults, and of farmers.

CONFUSING CLASSIFICATION.

The whole classification of graded milk needs revision. It should be considered more in the interests of the consuming public and of the producers of clean milk and not so much in the interests of the producers of unsafe or dirty milk. There are too many official designations, particularly as these designations leave the bulk of milk unlabelled. There are now four official designations of *raw* milk and two of *pasteurised* milk—i.e., six altogether. In addition, vendors may add "any old name" (e.g., "Nursery," "Children's," "Invalid") to their milk, although it may be dirty or unsafe.

Too many people have also assumed that by pasteurisation dirty, stale, or decomposing milk can be rendered fit for general consumption even by children. What is officially known as "Pasteurised Milk" may have been clean and fresh, or dirty and stale before it was pasteurised (i.e., no maximum bacterial count *before* pasteurisation is required). Filthy or old raw milk with a high bacterial count can never by mere pasteurisation be made into as good a class milk as reasonably clean raw milk. Then, too, at present a lot of milk which has been heated (but not properly pasteurised) is sold in London and other towns as raw milk. This deception discredits both raw and pasteurised milk.

The present officially recognised designations of milk are: Certified Milk; Grade A (tuberculin tested); Grade A; Grade A (pasteurised); pasteurised.

The number of grades should be reduced. The designations should also be simplified and should not mislead as they do now. For instance, most people to-day imagine that Grade A is the best grade of milk, whereas it is not even second, but is only the third grade. The designations are confusing. How can the ordinary buyer know which is best of the two grades "A., T. T." and "Certified"? What person going into a shop and being confronted with "A," "A., T. T." and "Certified" would know by these designations in what order of merit they should be placed? Simpler designations (e.g., 1, 2, or 3, or A, B, C) should be adopted.

REVISION OF DESIGNATIONS.

The present confusing classification tends to discredit the whole system of grading. Unless it be accurate it will not get public support or achieve its purpose, which is to let the public know what it is paying for. Until the public knows what it is buying the public will not buy as much as it should. Deceiving the public by giving dirty milk a high-sounding name does not help the dairy industry.

The present vendors of Grade A may kick if they are labelled B (or second Grade)—that is to say, if they are taken out of the apparently top class into which they have crept through a misleading designation. But no scheme can be successful so long as it is inaccurate. In any case, there are to-day still only a relatively small number of vendors of graded milk—i.e., there are about 150 licensed to sell Certified milk; 190 licensed to sell Grade A (tuberculin tested) milk; 500 licensed to sell Grade A milk out of a total of well over 100,000 dairy farms.

The longer we wait the more numerically powerful will the vested interests in existing designations become. The problem should be dealt with as soon as possible. But it is no good waiting for the irreconcilable vested interests to agree on a reclassification. Obviously they cannot do so. Yet it is the easy method hitherto adopted by badgered ministers and harassed officials to shelve the whole question.

Classification would be simplified if each separate class or grade covered both raw and pasteurised milk—i.e., the top grade might include both a raw and a pasteurised milk.

The importance of this is not always realised. If all pasteurised milk were lumped into one grade then the standard of cleanliness, &c., *before* pasteurisation would have to be low. But dirt, manure (and the high bacterial count which follows its presence in raw milk) is not really desirable in a beverage even if it is rendered innocuous by subsequent pasteurisation.

In America the tendency has been gradually to compel the pasteurisation of all the lower grades of milk. This took a long time to accomplish, because medical opinion was not at first agreed as to the value of pasteurisation, public opinion had not been educated, and because the trade had not the necessary plant.

LABELLING OF ALL MILK.

Ideally, all milk sold should be officially labelled. Everyone would then know what he was buying. Fancy (unofficial) designations are often dishonest and misleading. It is only the *labelling of all milk* that forces consumers to realise that there are differences in quality and to ask what the different designations mean. It is only the labelling of third-class milk as third-class that induces customers to ask for a higher grade, and so induces farmers to produce clean and safe instead of dirty and unsafe milk. Under such a system retailers are forced automatically to pass the pressure of customers on to the producers and to ask for first-class milk instead of second-class and for second instead of third-class. This is a cheaper and more effective way of obtaining improvement than by depending on a general inspection of farms though naturally some inspection is also needed. It may not be practical politics to label all milk now in the whole country, but the aim of the Government should be to carry such a policy as soon as possible (say in 10–15 years time).

But farmers will resist the compulsory labelling of all milk unless they receive a higher price for the superior grades. To-day most of the milk would be in the lowest grade, and there is really no inducement to farmers to take the extra trouble and to put themselves to the extra expense of producing cleaner milk. It may be hard and costly to produce the top grade: it is relatively easy to raise one's milk from the third to the second grade. Medical opinion can help by making the public realise (1) that milk is a very cheap food, (2) that clean and safe milk is worth a higher price than dirty milk, and (3) that this higher price will still give an article whose nutritional value is cheap by comparison with eggs, beef, fish, &c. When the public is safeguarded more milk will be bought and real propaganda to induce people to drink more liquid milk can be embarked upon.

The expenditure to-day on advertising milk is ridiculously low. £265,000 is spent annually in advertising in the press those patent foods of which milk is merely a constituent. £38,000 is spent on advertising preserved milk, but only £10,000 is spent on fresh milk! Everyone is informed from countless hoardings that a certain stout is good for him, but he is not told that milk is good (and better) for him or her and their child.

THREE NEW GRADES.

What, then, should be the new classification? We should probably look forward to there being ultimately (say in 10–15 years time) only two grades. But it is not feasible to get this now. So the immediate classification must be such that it does not interfere with the ultimate goal.

I think that at the outset there would have to be three grades. The top grade should be (humanly speaking) "absolutely safe." This top grade sets the standard for the lower groups. It is essential to have this grade even though the percentage of milk included in it is at first small compared with the total supply. The bacterial content of the raw milk in this grade must be sufficiently low to guarantee that the milk will keep sweet in summer. Probably nothing over 30,000 bacteria per c.cm. meets this requirement. This raw milk must also be bottled on the farm to prevent any chance of contamination. But this top grade should also include a pasteurised milk. This latter should be from milk which had always been clean, sweet, and fresh—i.e., it must never have had a high (? not over 200,000) bacterial count before pasteurisation and must be from physically examined (? tuberculin tested) cows.

The second grade should be "reasonably good" milk. The raw milk might have a maximum bacterial count of about 750,000 when delivered. It need not be bottled on the farm. Possibly after some years the raw milk belonging to this grade might be dropped as though reasonably safe (i.e., from physically examined cows and with a relatively low count), it could not be absolutely guaranteed. If, however, it were from tuberculin-tested cows it might continue.

The pasteurised milk in this second grade might have a maximum bacterial count of 50,000 when sold to consumers and 750,000 (or 1,000,000) before pasteurisation.

The third grade would be milk which did not come up to the standards of either of these two grades. At first there would have to be raw milk in this third grade, but as soon as possible it should be all pasteurised. In time as the industry improved the whole of this third grade might be eliminated. For a time, however, it would certainly be a necessary group.

CONCLUSION.

I have indicated what might happen in 10–15 years over the whole country after conditions had improved. Meantime I suggest that we should adopt the procedure associated with the development of public health, education, &c.—namely, to empower progressive local authorities to go ahead. After having revised the designations of milk on the lines discussed, Parliament should pass an Act empowering local authorities (county borough councils, borough councils, and perhaps urban district councils) to adopt model milk regulations. These regulations should enable local authorities to compel all milk sold within their area to be labelled in accordance with the official designations. The local authorities might also be empowered by the Order to require all milk offered for sale for delivery to consumers to be delivered in sealed vessels.

Let me summarise the legislative and administrative steps on which the readers of THE LANCET in particular might concentrate: 1. Revise the designations of milk. 2. Empower local authorities to compel all milk sold in their areas to be labelled. 3. Ten to fifteen years hence label all milk.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

A MEDICAL POLICY.

Dr. Jivraj N. Mehta, head of the large and well-equipped independent medical college in Bombay, is one of the leading figures of the medical profession in western India. He recently addressed the Calcutta Branch of the Indian Medical Association on the question of evolving a medical policy for the country, and his views may be taken as representative of a large section of Indian opinion. The subject matter of his address fell under five heads: the provision of medical relief and its organisation; medical education and the standard to be aimed at; medical registration; research; and public health. Dr. Mehta would cut down the existing government services, except in departments such as public health, where it is admitted that a government agency is essential. He quotes the practice of other countries, in which the great bulk of hospital work is carried on by voluntary agencies, and would like to see a great extension of the voluntary system in hospitals. In medical education he emphasises the desirability of providing real specialists, and complains of the existing system—which, however, is rapidly disappearing—of appointing service professors, who may or may not have specialised adequately in their subjects. He draws attention to the need of appointing full-time incumbents for such subjects as anatomy, physiology, and pathology. Here again in many cases action was taken in the government schools long ago. Reviewing the existence of two distinct classes of practitioners—graduates and licentiates—Dr. Mehta has come to the conclusion that it is not at present possible to maintain a uniform standard, and that for some time to come, at all events, it will be necessary to continue both types. But he is in favour of lengthening the course for licentiates, and of diminishing the gulf which at present exists between the two classes. He would also have a minimum standard for registration throughout the country. Dr. Mehta was a sharp critic of the General Medical Council in the controversy over the recognition of

Midwives Board examination was extended from six to twelve months (except for trained nurses) and the curriculum was also somewhat extended. Furthermore the campaign for the lessening of maternal mortality has undoubtedly had a beneficial effect on the midwife's outlook while her fees have increased to from 16*s.* to 30*s.* in East London and from 30*s.* to 50*s.* in West London. Finally it is agreed that throughout the years there has been a growing feeling of professional pride, spread by intercourse through the Midwives Institute and through discussions following the Council's lectures. The old jealousy and undercutting in fees which kept midwives apart is now a thing of the past.

LOCAL AUTHORITIES AND ADVICE ON BIRTH CONTROL.

In a memorandum (153/M.C.W.) issued to maternity and child welfare authorities the Minister of Health states that the Government have had under consideration the question of the use of institutions which are controlled by local authorities for the purpose of giving advice to women on contraceptive methods.

USE OF EXISTING CENTRES.

So far as maternity and child welfare centres (including antenatal centres) are concerned, these centres can properly deal only with expectant mothers, nursing mothers, and young children, and it is the view of the Government that it is not the function of the centres to give advice in regard to birth control and that their use for such a purpose would be likely to damage the proper work of the centres. At the same time the Government consider that, in cases where there are *medical grounds* for giving advice on contraceptive methods to married women in attendance at the centres, it may be given, but that such advice should be limited to cases where further pregnancy would be detrimental to health, and should be given at a separate session and under conditions such as will not disturb the normal and primary work of the centre. Accordingly any proposal for the use of these centres for giving birth control advice in other cases will not be sanctioned.

SPECIAL CLINICS.

Local authorities, it is stated, have no general power to establish birth control clinics as such, but under the Notification of Births (Extension) Act, 1915, which enables local authorities to exercise the powers of the Public Health Acts for the purpose of the care of expectant mothers and nursing mothers, it may properly be held that birth control clinics can be provided for these limited classes of women. Having regard to the acute division of public opinion on the subject of birth control, the Government have decided that no departmental sanction which may be necessary to the establishment of such clinics for expectant and nursing mothers shall be given except on condition that contraceptive advice will be given only in cases where further pregnancy would be detrimental to health.

Under the Public Health Acts, local authorities have power to provide clinics at which medical advice and treatment would be available for women suffering from gynæcological conditions. But the enactments governing the provision of such clinics limit their availability to sick persons, and the Government have decided that any departmental sanction which may be necessary to the establishment of such clinics shall be given only on the following conditions: (1) that the clinics will be available only for women who are in need of medical advice and treatment for gynæcological conditions, and (2) that advice on contraceptive methods will be given only to married women who attend the clinics for such medical advice or treatment, and in whose cases pregnancy would be detrimental to health.

MENTAL HOSPITAL REPORTS.

The Glengall Hospital at Ayr always turns out its annual report with commendable promptitude. On Dec. 31st last it had 653 patients in residence; half of the 200 cases admitted during the year were in a precarious condition, thus taxing the nursing and accommodation in the infirm wards to the utmost. The medical superintendent remarks on the curious anomaly whereby the old-age pension of a certified patient is not available for his maintenance. The recovery-rate was 28 per cent. and the death-rate 13·2 per cent. No less than 22 men and 10 women succumbed to general paralysis during the year, while senile decay accounted for 21 per cent. of the deaths. The general health has been very good, the only infectious disease being one case of diphtheria in a laundry-maid. About four-fifths of the patients were actively employed, while 26 had parole beyond and 37 within the grounds. The visiting commissioners remark on the neatness and orderliness of the patients despite the somewhat overcrowded condition of the institution. Four nurses and two attendants obtained their R.M.P.A. certificates during the year and 48 per cent. are now fully certificated.

The Aberdeen Royal Mental Hospital's report also appears promptly. There were 860 patients on the register on the last day of 1930, including 27 voluntary boarders. Exhaustion was a striking feature in many of the cases on admission. There was a recovery-rate of 21·71 per cent. and a death-rate of 5·66 per cent. The medical superintendent remarks that even now many cases that might have been cured earlier arrive at hospital too late for anything to be done. The general health was good. There was one case of dysentery. The dentist visited weekly and extracted 532 teeth, filled 28 more, and fitted 19 dentures. The occupational therapy department is continuing its work with success and enthusiasm, and a number of patients work out of doors in the grounds. The new verandah is proving very satisfactory as a small sanatorium. A new nurses' home was opened in the summer and the directors have purchased a house for private patients suffering from early and nervous mental disorder.

The Royal Edinburgh Hospital at Morningside is the third Scottish hospital to publish its annual report before the end of February. At the end of last year there were 804 patients at the Royal Edinburgh Hospital and 13 out on trial; there were 57 in the associated nursing homes and 39 at the Jordanburn Nerve Hospital. During the year 349 new patients were seen at the out-patient clinic and the social service worker paid 492 visits. The medical superintendent, in his address, describes the work that is now being done for mental health in Edinburgh. He characterises the trend of treatment to-day as "de-asylumisation" and "hospitalisation." He describes the university clinic for children, where behaviour problems of all kinds are studied; the out-patient clinics; the Jordanburn voluntary hospital; the social service house, and the teaching work at the university. During the last 12 years over £15,000 has been spent.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED *MARCH 21ST, 1931.*

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 219 (last week 171); scarlet fever, 1700; diphtheria, 1045; enteric fever, 22; pneumonia, 2234 (last week

2033); puerperal fever, 49; puerperal pyrexia, 150; cerebro-spinal fever, 84 (last week 59); acute poliomyelitis, 3; encephalitis lethargica, 23; continued fever, 1; dysentery, 14; ophthalmia neonatorum, 97. No case of cholera, plague, or typhus fever was notified during the week.

In the West Riding of Yorkshire 35 cases of cerebro-spinal fever were reported as compared with 26, 28, 21, 41, 22, 12, 19, 5, 11, 5, and 5 in the previous weeks of the year (working backwards). Of these, 7 occurred in four large towns, 18 in ten boroughs and urban districts, 10 in three rural districts.

The number of cases in the Infectious Hospitals of the London County Council on March 24th–25th was as follows: Small-pox, 231 under treatment, 10 under observation (last week 192 and 2 respectively); scarlet fever, 1221; diphtheria, 1735; enteric fever, 172; measles, 126; whooping-cough, 438; puerperal fever, 33 (plus 15 babies); encephalitis lethargica, 121; poliomyelitis, 2; "other diseases" 182. At St. Margaret's Hospital there were 12 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (2) from enteric fever, 75 (1) from measles, 5 (0) from scarlet fever, 59 (18) from whooping-cough, 52 (5) from diphtheria, 73 (20) from diarrhoea and enteritis under two years, and 365 (44) from influenza. The figures in parentheses are those for London itself.

Three death from meningococcal meningitis occurred in London, 1 each under one year, from 2–5 and from 15–25 years. The deaths from typhoid were reported from West Ham, Liverpool, and Sunderland. Twelve fatal cases of measles were reported from Liverpool, 8 from Birmingham, 6 from Newcastle-on-Tyne. Liverpool and Newcastle each reported 6 deaths from whooping-cough, Manchester 5. Diphtheria claimed 5 victims at Liverpool, 3 at Birmingham. Eleven deaths from diarrhoea were reported from Birmingham, 8 from Stoke-on-Trent. The 321 fatal cases of influenza outside London are scattered over 83 great towns: 25 were reported from Birmingham, 20 from Sheffield, 19 from Manchester, 14 from Derby, 12 each from Bristol and Stoke-on-Trent.

The number of stillbirths notified during the week was 303 (corresponding to a rate of 43 per 1000 births), including 51 in London.

CORRESPONDENCE

APHTHOUS ULCERS.

To the Editor of THE LANCET.

SIR,—Would you allow me to make use of your columns to inquire whether any of your readers can give me any really useful information as to the treatment, either local or general, of aphthous ulcers of the
uth? These are commonly described as commencing
vesicles, possibly herpetic in origin, which subse-
ntly break down to form the typical grey ulcer
undermined edges. However, they frequently
to occur where the cheek is accidentally bitten.
nd from a friend of mine, who is a patho-
that bacteriological investigation offers no
atter of type of infection.

are extremely painful, and apparently

I am, Sir, yours faithfully,

F. A. PHILLIPS.

Lower Sloane-street, S.W., March 30th, 1931.

CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—The statement in my letter to which Lieut.-Colonel H. M. Perry refers was that it was lamentable that at the present time type sera are not available in this country either for diagnostic *or for treatment purposes.* I had in mind the country in general, not the Army in particular. I did however point out the great advance in the treatment of cases in the Army rendered possible by Dr. M. H. Gordon's researches and the typing of the organisms. Colonel Perry makes no reference to the treatment of the disease by type sera. He simply states that type sera had been available in the Army for the purposes of diagnosis. It would be interesting, therefore, if he would state (1) whether type sera have been available *for treatment* for any of the cases which have occurred in the recent outbreaks in the Army; (2) the types of meningococci which were found in these cases and the case-mortality. If the cases have only been treated with polyvalent serum, we should have an excellent means of comparison of the results now obtained in the Army with those treated with univalent serum mentioned by Dr. Gordon in his letter of Feb. 28th.

I am, Sir, yours faithfully,

A. H. G. BURTON,

March 25th, 1931. Medical Officer of Health, Ilford.

MEDICAL OFFICERS IN THE AIR FORCE.

To the Editor of THE LANCET.

SIR,—In your Parliamentary Correspondent's short report last week (p. 733) of Mr. Montague's remarks in the House of Commons on the deficiency of medical officers in the Air Force there are two errors which though apparently trifling in themselves give a wrong impression of the Service. In the report it is stated that "the deficiency of regular medical officers was, he would see that they were inserted at a later stage.

The amendment was by leave withdrawn.

OTHER AMENDMENTS.

On Clause 16 (prohibitions and regulations with respect to sale of poisons),

Viscount HEREFORD moved an amendment to secure that when poisons were sold in chemists shops under Part II. of the Bill they should be sold under qualified supervision.

Lord PONSONBY accepted the amendment which was agreed to.

Lord COZENS-HARDY moved an amendment to restrict the conditions in paragraph (1) Subsection (2) as to the sales of pharmacies, and to exempt medical men from their application altogether. So far as he could understand this rather complicated clause its affect would be that a doctor who was prescribing for an uninsured person would have to make certain records and keep a book which a doctor prescribing for the millions of insured persons would not have to do. It seemed an unnecessary task.

Lord PONSONBY said this amendment would really be going back on the present position, because the existing law in the Pharmacy Act, 1869, already required medicines prescribed by a doctor to a patient to be distinctly labelled with the name and address of the doctor, and the ingredients to be entered with the name of the person to whom they are supplied in a book to be kept by the doctor for the purpose. This point was discussed at the Home Office conference, and on the whole the representatives of the medical profession preferred not to have any alteration in the present law.

The amendment was negatived.

Lord PONSONBY moved amendments which he said were intended to make it clear that subparagraph (c) in paragraph (II.) of Subsection (3) did not apply to medical practitioners; and in the second place to relax the conditions as to the recording of details in a book in cases where the medicine supplied was a repeat.

The amendments were agreed to.

On Clause 17 (exemption with respect to sales wholesale and sales to certain persons),

Lord PONSONBY moved two amendments. The first amendment specially exempted sales to a doctor from the general requirements of Clause 16. The second amendment proposed that sales by persons doing a substantial business in poisons or persons doing a substantial business in supplying poisons for use in industry should be exempt subject to rules made for the purpose with relation to use in trade or business.

The amendments were agreed to.

On Clause 24 (interpretation),

The Earl of HALSBURY moved an amendment to provide that the word "poison" should be deemed to include any substance which in the opinion of the Poisons Board was dangerous if taken without medical supervision or prescription. He said he would not press the amendment if Lord Ponsonby would undertake to consider the matter before the Report stage.

Lord PONSONBY said he would be much obliged to the noble earl if he would leave the matter like that. He certainly intended to have this matter gone into very carefully, but he would point out that they had to steer a rather difficult course, because they had the medical profession watching very closely, and they had to carry the medical profession with them as well. He did not hold out any hope that he would be able to make any drastic alteration, but he would certainly look into the matter.

THE POISONS BOARD AND ITS CONSTITUTION.

The amendment was by leave withdrawn.

On the first schedule (constitution of Poisons Board),

The Earl of HALSBURY moved to leave out the first paragraph which states that the Board shall consist of 14 members, and that the Secretary of State may from time to time appoint additional members not exceeding four in all. He said that he was anxious to maintain the balance of the Board so that the majority vote would lie with the experts and not with Whitehall officials. Their lordships had thought fit to give complete and absolute control to the Secretary of State. Why should they not have at least a Board which was controlled by experts? A firm in Constantinople were employing nothing but research chemists in order to see if they could discover some veronal-medinal group. The Departmental Committee went out of their way to say something about that question. For lack of proper advice it might be that whatever this firm discovered would not be placed on the poisons list. There would be a long delay before the Poisons Board dealt with it, and eventually the drug manufacturers would have something else up their sleeve to put on the market, and so the matter would go on. He urged that they ought to have on the Poisons Board somebody representing the Chemical Society who could advise as to whether any particular substance that came on the market should be put in the poisons schedule.

Lord PONSONBY said the matter raised by the noble earl was important, but whatever political party the Home Secretary might belong to he might be trusted in these matters to act with the greatest care. It was not likely that any Home Secretary would appoint Tom, Dick, or Harry to the Board. The four additional members would not be officials. With regard to the medical profession the matter was discussed at the Conference at the Home Office, and it was agreed that there should be an additional representative of the medical profession nominated by the British Medical Association. The constitution of the Board as it stood in the Bill was satisfactory, and would meet what the noble lord felt to be necessary.

The amendment was by leave withdrawn.

The Committee stage of the Bill was concluded.

YARMOUTH NAVAL HOSPITAL BILL.

ON Friday, March 27th, Mr. AMMON (Parliamentary Secretary to the Admiralty) moved the second reading of the Yarmouth Naval Hospital Bill, which, he said, was non-controversial, and had passed through the House of Lords. It was urgently needed both by the Admiralty and the Ministry of Pensions. The main object of the Bill was to remove any doubt regarding the legal position of the hospital in which there were now accommodated mental patients.

Mr. MACPHERSON opposed the Bill on the ground that it was an inroad into the rights and liberties of the subject. Unless there was a promise of radical amendment in Committee he would vote against the measure.

Major TRYON said that the House was entitled to receive a good deal more information about the Bill.

Mr. ERNEST BROWN moved the rejection of the Bill.

Lieut.-Colonel FREMANTLE thought that the Bill ought to be passed as a provisional measure, subject to a full explanation that it was intended to improve the hospital in the interests of the patients.

Mr. AMMON, replying to the debate, said that this hospital had always been a voluntary one. There was no question of compelling patients to go there against their will, or against the wish of their friends and relatives.

The motion for rejection was withdrawn, and the Bill was read a second time and committed to a Committee of the whole House. The necessary money resolution was agreed to in Committee.

COMPULSORY VACCINATION.

In the House of Commons on March 30th Mr. GROVES presented a Bill to repeal the law relating to compulsory vaccination.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 25TH.

Contagious Disease in the Navy.

Lieut.-Colonel Fremantle asked the First Lord of the Admiralty what reduction there had been in the incidence of contagious diseases in the Navy during the last six years; and what steps were taken especially to bring entrants and lads in the training establishments under the influence of intensive and comprehensive educational schemes with a view to the prevention of such diseases.—Mr. Ammon replied: I presume that by "contagious diseases" venereal diseases are referred to. The reduction (or increase) in the incidence of these diseases in the Navy, during the last six years, is set forth in the following table:—

Incidence of Venereal Disease (Fresh Infections) for the years 1924–29.

Year.	No. of cases.	Ratio per 1000 of strength.	Increase or decrease compared with previous year.
1924	5987	68·32	10·19 decrease.
1925	5412	60·16	8·16 "
1926	5184	57·18	2·98 "
1927	5341	57·28	0·10 increase.
1928	5160	56·81	0·47 decrease.
1929	5312	61·91	5·13 increase.

Comprehensive educational schemes are in force in the training establishments. In the general depots, all new entries receive special instruction. In boys' training establishments, very special care is taken to ensure adequate and suitable instruction in sex hygiene. This instruction forms part of the general scheme of moral training, and is carried out, in close coöperation, by the divisional executive officers, the chaplains and medical officers of the establishments concerned. Moreover, thorough instruction, especially with regard to venereal diseases and their dangers, is imparted to those boys before they are drafted to sea-going ships.

Lieut.-Colonel Fremantle: Is it not a fact that the rate of reduction of these most serious diseases has stopped during the last six years, and that the Admiralty are taking no special steps to deal with the situation?

Mr. Ammon: No, I think that the hon. Member will find that that is not quite borne out by the information.

Lieut.-Colonel Fremantle: Are the Admiralty taking full steps to avail themselves of the offer of the British Social Hygiene Council to give them help which has been so useful elsewhere?

No further answer was given.

Dead Children Found in Hong-Kong Streets.

Mr. Graham White asked the Under-Secretary for the Colonies whether, seeing that an average of more than 1300 bodies of dead children were picked up in the streets of Hong-Kong each year, he would call for a report from the governor of Hong-Kong as to what verdicts had been given at the inquests held upon these children; and what administrative steps were being taken to bring to trial those who were alleged to be responsible.—Dr. Shiels replied: My noble friend inquired into this matter some little time ago. In a despatch dated May 22nd, 1930, the governor informed him that every abandoned corpse is removed to the public mortuary for post-mortem examination, but in almost every case no cause is discovered for suspicion that the death resulted from other than natural causes. Every case is reported to the coroner, but the governor states that in no single instance in 1928 did the coroner see any necessity for a formal death inquiry. In the circumstances my noble friend does not propose to call for a further report of the nature suggested by the hon. Member.

Mr. White asked Dr. Shiels whether, whatever might be the causes, he could not assure the House that some steps would be instituted which would put an end to a state of things which without exaggeration was appalling.

Dr. Shiels: I quite agree that it is very unsatisfactory. I understand that in the main these happenings are due, in some cases, to fear of inquiries as to infectious disease orders, and in other cases to save the expense of burial. My noble friend has gone into the matter and drawn the governor's attention to it, and I believe that everything possible is being done.

Maternal Mortality in India.

Miss Rathbone asked the Secretary for India the rate of maternal deaths per 1000 confinements in British India during last year, or for the most recent year for which figures were available.—Mr. Wedgwood Benn replied: Figures are not available for the whole of British India. But to take a few illustrative cases, the ratio of maternal deaths per 1000 live births in 1927 was 12 for Madras Town, and 5·3 for Madras Presidency; 5 for Bombay City and 5·4 for the Presidency. When copies of the Public Health Commissioner's Report for 1928 are received I will have one placed in the library.

Miss Rathbone asked if the right hon. gentleman had any reason to think that these figures could be complete in view of the statement of the representative of public health in Madras that 20,000 is a very moderate estimate of the number of maternal deaths?

Mr. Benn said he had given the official figures, which he had no doubt were accurate.

THURSDAY, MARCH 26TH.

Abolition of Night Baking.

Miss Lee asked the Home Secretary when it was proposed to proceed with legislation to abolish night baking.—Mr. Clynes replied: It is the intention of the Government to deal with this matter in the Factories Bill.

Convictions for Drunkenness.

Captain Crookshank asked the Home Secretary how many convictions for drunkenness there were in Carlisle in 1928, 1929, and 1930.—Mr. Clynes replied: The figures are shown in the annual volumes of licensing statistics, and for 1928 and 1929 were 60 and 56. The volume for 1930 is not yet complete, but the figures may be given provisionally for Carlisle as 81.

Domiciliary Treatment of Sick Poor.

Dr. Hastings asked the Minister of Health the number of local authorities that have, in accordance with the provisions of the Local Government Act, 1929, assigned to their public health committees the domiciliary treatment of the sick poor.—Miss Susan Lawrence replied: Provision to this effect has been made in the administrative scheme of eight local authorities.

Maternity and Child Welfare Services.

Mr. Day asked the Minister of Health whether he could state the estimated total grant payable by his department during the present financial year towards maternity and child welfare services, giving the comparable figures for 1928.—Miss Susan Lawrence replied: I would remind my hon. friend that under the Local Government Act, 1929, separate grants for maternity and child welfare services, other than the training of midwives and health visitors, ceased to be payable in respect of any year after the financial year 1929–30. The amount of the discontinued grant paid for these services during the year 1928–29 was £1,047,890, and this amount was included in determining the loss on account of grants under the Act.

MONDAY, MARCH 30TH.

Washington Convention.

Sir T. Inskip asked the Prime Minister whether it had been decided by H.M. Government to ratify the Washington Hours Convention as it stood without any reservation, condition, or statutory interpretation.—Mr. MacDonald replied: The Government's policy is to ratify the Convention without reservation or condition. The Convention requires legislation to give it statutory effect, and the Hours of Industrial Employment Bill has accordingly been introduced.

Hours of Industrial Employment.

Sir T. Inskip asked the Prime Minister whether it was proposed to take any further stages of the Hours of Industrial Employment Bill at an early date; and whether he could make any statement as to the obstacles which had prevented any progress with the Bill since its re-introduction last November.—Mr. MacDonald: The Government proposes to take the further stages of the Hours of Industrial Employment Bill at the earliest practicable date. The hon. and learned Member may be aware that pressure of other business has made it impossible hitherto to proceed with the Bill.

Patent Medicines.

Dr. Hastings asked the Secretary to the Treasury whether he would order the reprinting of the Report of the Select Committee on Patent Medicines, 1914.—Mr. Pethick-Lawrence (Financial Secretary to the Treasury): The cheap edition of the report of the Select Committee on Patent Medicines, 1914, has been out of print for some years, and there is no evidence before me that there is a substantial demand to justify a reprint. The full edition, containing the proceedings and minutes of evidence, is still available.

Production of Opium.

Mr. CAMPBELL asked the Home Secretary whether, at the conference to be convened by the League of Nations at Geneva next May on the limitation of the manufacture of dangerous drugs, the production and distribution of opium would be included in the purview of the conference.—Mr. SHORT: No, Sir. The question of limiting the production of raw opium is outside the scope of the conference.

Dumping of Refuse.

Mr. MILLS asked the Minister of Health if he intended to bring in a Bill to put an end to the nuisance and annoyance caused by the dumping of house refuse by one sanitary authority in the area of another sanitary authority without the latter authority's consent.—Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health): It is not proposed to bring in a Bill this session for dealing expressly with the dumping of refuse. I may say, however, that the Town and Country Planning Bill recently introduced will strengthen the hands of the planning authorities in preventing or controlling the use of land for such a purpose. Local authorities may also prevent nuisance if by-laws dealing with the disposal of refuse are made betimes and strictly enforced.

Over Seven Years' Cases.

Sir F. HALL asked the Minister of Pensions the number of applications submitted from ex-Service men for pension since the decision of the Government to abolish the seven years' limit; the number of such applications which had been admitted and pensions granted; and whether the Government would make a further notification of their decision in respect of the over seven years' cases in order that ex-Service men might know that, notwithstanding the lapse of seven years, they might, if satisfied that they had good grounds, apply for disability pension.—Mr. HAYES replied that during the 15 months since November, 1929, some 22,800 applications had been received in respect of fresh disabilities, including an undetermined number of renewed applications. During the same period, 1210 cases had been recognised by way of medical treatment or the award of compensation in the form of pension or other pecuniary grant. Full publicity had been given to the decision referred to, which the Minister of Pensions had every reason to believe was well known, and a further announcement at the present time would, in his view, serve no useful purpose.

MEDICINE AND THE LAW.

The Christie Will Case.

Lord Merrivale's judgment in the lengthy and expensive litigation in the Christie case is an admirable illustration of the law of testamentary capacity. The law assumes the sanity of a testator and—at any rate until Miss Rathbone's Wills and Intestacies (Family Maintenance) Bill is passed—places no restriction on his complete freedom of disposition. An eccentric will, or a harsh will which capriciously disinherits wife and children in violation of moral obligations, is not invalid provided that the testator has what lawyers call a "sound disposing mind." Lord Merrivale has repeated with approval the observations of Chief Justice Cockburn in Banks *v.* Goodfellow in 1870. The testator must not only be able to understand that by his will he is distributing his property to one or more objects of his regard. He must also have capacity to comprehend and recollect the extent of his property and the nature of the claims of others whom by his will he is excluding from participation. It is essential that no disorder of the mind should poison his affections, pervert his sense of right or prevent the exercise of his natural faculties. No insane delusion must influence his intention in disposing of his property and bring about a disposition which, had the mind been sound, he would not have made. In Mr. Christie's case the President found that the testator was a man of vigorous health and dominating personality until 1914 when he suffered from pneumonia. In 1918 he had a stroke; later, other attacks followed and his disability increased. Speech became difficult; it was limited to single words which were not easily produced. In June, 1924, he was certified as of unsound mind and was removed to a mental home though he was taken away soon afterwards. In August his wife was appointed receiver of the estate. There was local indignation and efforts were made to set aside the receivership order. The Lunacy Commissioners sent visitors, so that considerable expert evidence was available later. In January, 1925, Mr. Christie made a will disinheriting his wife and son. The solicitor, who had taken his instructions, adopted the unusual but prudent course of causing four medical practitioners to be present at the execution of the will. Two of the doctors witnessed the signature; all four vouched that they were satisfied of his capacity. They had heard the will read over to him; they had been encouraged to ask questions and they had tested his knowledge of what he was doing. A number of local witnesses gave evidence at the trial that the squire, as they called him, was sane in spite of his aphasia, that they themselves always understood what he wished to say, that he in turn understood them, that he never said or did a foolish thing, that he was a shrewd judge of cattle, and so on. Lord Merrivale was evidently impressed by this evidence. It was not, he said, till he finally heard the evidence of the wife in the later stages of the trial that he doubted whether Mr. Christie had known and approved the contents of his 1925 will. After hearing her evidence the President found himself unable to be certain of the testator's sound disposing mind; the burden of proof rested upon the parties who were propounding the 1925 will; that burden was not discharged, and so Lord Merrivale pronounced against the 1925 will and in favour of an earlier will of 1901 under which the wife was made sole executrix and universal legatee. The President found that the testator, by reason of the progressive deterioration of the brain, due to arterio-sclerosis, was wholly insane and unaccountable for his actions in 1924. "I am satisfied that Mr. Christie was suffering from a progressive disease which affected his mental faculties; it deprived him of the means of knowledge, of the scope of knowledge and of the capacity for judgment which were necessary to give him testamentary capacity. With regard to his wife and son, whom the will of 1925 was intended to dispossess, he had an insane delusion that they hated him." This last sentence, we may assume, contained the crucial finding. A mere mistaken conclusion by the husband that his wife and son hated him would not have invalidated the will. But, in the language of Banks *v.* Goodfellow, disorder of the mind had poisoned the testator's affection, perverted his sense of right, and prevented the exercise of his natural faculties.

Medical practitioners who have the misfortune to be concerned in disputes of this nature will know the bitterness which can be reflected in forensic comment and cross-examination. It was suggested that the medical adviser on whom the wife had relied in the measures taken for Mr. Christie's health, safety, and supervision, had been complacently ready to certify insanity without proper ground, and had assisted the wife to reduce her husband to a state of pitiful ignominy and hopelessness for her own mercenary ends. Lord Merrivale's extensive judgment takes the opposite view. He makes it clear that the wife and doctor "were doing their best in circumstances of indescribable difficulty, and believed what they have since come here and said."

MEDICAL NEWS

University of Oxford.

On March 28th the following degrees were conferred :—

D.M.—D. G. Leys and R. Lewthwaite.
B.M.—T. M. Davie, E. Harvey, and K. N. Irvine.

Royal College of Physicians of London.

At a meeting of the College on March 30th Lord Dawson of Penn was elected President. Sir John Rose Bradford, as retiring President, delivered the presidential address for the past year.

Lord Dawson was appointed to represent the College at the forthcoming Centenary Celebrations of the University of Leeds on June 30th and July 1st, and Dr. William Hunter was nominated to represent the College at the forthcoming congress of the Universities of the Empire to be held in London and Edinburgh in July.

The undermentioned diplomas were granted, jointly with the Royal College of Surgeons, to the following candidates :—

Diploma in Tropical Medicine and Hygiene.—N. J. Abbensetts, Mohammad Akram, James Cairns, H. G. Calwell, C. P. Campion, M. M-D. Chughtai, G. J. Clarke, Annie E. Connan, Sonti Dakshinamurty, David Ellis, Mohamed El Huseini, H. G. Floyd, J. R. Jensen, W. P. Jones, Rajmal Kasliwal, Ah Ma, T. T. Mackie, E. W. Martindell, Alexander Mearns, P. B. P. Mellows, Myrtle Noronha, Socrates Noronha, Muttukumaru Sangarapillai, D. W. Semmens, Saravanamuttu Thambiah, R. B. Wallace, Janet Welch, Ethel M. Weir, G. F. West, and W. A. Wilson.

Diploma in Ophthalmic Medicine and Surgery.—Shaikh Atta-Ullah, B. P. Danard, H. D. Dastoor, T. E. Davies, John Foster, Dorothy Guest, James Hill, Herbert Kaitz, Mohanlal Kalra, J. G. Kshatri, Ivan Marais, G. R. Marcano, M. S. Mehkri, H. G. Nimbalker, K. J. O'Day, V. P. Patel, F. G. Roberts, and A. L. Sutherland.

The College will be closed from Friday, April 3rd, to Tuesday, April 7th, both days inclusive.

University of Leeds.

At recent examinations the following candidates were successful :—

M.D.

S. J. Hartfall (with distinction), J. C. Lamont, and W. A. D. Lawson.

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—H. Agar, Doris B. Brown, H. Featherman, E. Gledhill, J. S. Gourlay, Gwendolen Harrison, H. Hart, F. R. W. Helmsley, Ruth Hooton, E. James, M. Lask, J. Littlewood, I. Macpherson, J. Q. Mountain, I. Rosenberg, M. Rosenthal, L. W. Russell, M. Shankhla, S. Strasburg, S. Suvi, and J. Taylor.

Part II. (New Regulations).—J. E. Abell, P. R. Allison, E. L. Brittain, J. M. P. Clark, J. L. Coleman, F. B. T. T. Drake, J. Fielding, L. Glick, R. A. Hall, G. P. Holderness, J. M. Holmes, G. Hyman, G. Marquis, H. Mattison, M. R. Potter, L. J. Richmond, S. Rosenbloom, N. Ross, J. Scholefield, B. Schroeder, P. Science, J. Shapiro, and F. R. Staub.

Part III. (New Regs.)—P. R. Allison (First Class Honours), J. E. Abell, E. L. Brittain, J. M. P. Clark, J. L. Coleman, F. B. T. T. Drake, J. Fielding, R. A. Hall, G. P. Holderness, G. Marquis, M. R. Potter, L. J. Richmond, S. Rosenbloom, N. Ross, J. Scholefield, P. Science, J. Shapiro, and F. R. Staub.

Part III. (Old Regs.)—J. Kak.

FINAL EXAMINATION FOR B.CH.D.

M. R. Hollings.

FINAL EXAMINATION FOR L.D.S.

I. Levey, A. B. Levie, Reca R. Lieberman, S. Slater, P. W. Thornton, and J. Todd.

D.P.H.

H. S. Carter and R. C. Holderness.

University of London.

At a meeting of the Senate on March 25th it was resolved to institute a university chair of experimental pathology tenable at the Cancer Hospital (Free).

London Light and Electrical Clinic.

At the annual general meeting of the British Humane Association recently held it was reported that the London Light and Electrical Clinic continues to be the main activity of the Association. There was an increase of 45,000 treatments over the previous year, and out of the 173,000 treatments administered some 5000 were given free to people unable to afford any contribution. The Private Clinic has, it was stated, given satisfactory results and has fully justified the experiment. Among the new features during the year has been the extension of the laboratory side of the work, and Sir Leonard Hill has been appointed hon. research director, with Dr. A. Eidinow to assist him. The use of the clinic as a training centre had been developed by the institution of post-graduate courses for doctors, and arrangements are being made to appoint visiting physicians to the clinic.

University of Manchester.

At a recent examination for the Diploma in Public Health (Part II) Dr. Elsie Catlow was successful.

Fellowship of Medicine and Post-Graduate Medical Association.

The annual general meeting of this association will be held at 1, Wimpole-street, London, W., at 5.30 P.M., on Monday, April 13th.

Royal Navy Medical Club.

The annual dinner of this club will take place at the Trocadero Restaurant, Piccadilly-circus, on Thursday, April 16th, at 7.30 for 8 P.M. Members who wish to be present are asked to inform the hon. secretary at Queen Anne's Chambers, Tothill-street, London, S.W.1, not later than seven clear days beforehand.

Auxiliary R.A.M.C. Funds.

The annual meeting of the members of the Auxiliary R.A.M.C. Funds will be held at 5 P.M. on Friday, April 17th, at 11, Chandos-street, Cavendish-square, W.1, when the annual report will be presented and the officers and committee for the current year elected.

West London Medico-Chirurgical Society.

The Cavendish lecture of this society will be delivered on June 5th at the Kensington Town Hall by Prof. Julian Huxley, whose subject will be Development in Relation to Heredity and Evolution. The next meeting of the society will be at the De Vere Hotel, Kensington, on April 10th.

Journées Médicales de Bruxelles.

The eleventh meeting of this congress will be held at Brussels from June 20th to 24th under the presidency of Prof. Auguste Ley. It is dedicated to the memory of Fernand Widal. The secretary-general is Dr. Beckers, 145, rue Belliard, Bruxelles.

Medical Superintendents' Society.

The annual dinner was held at the Holborn Restaurant, London, on March 27th. Eighty-four members and guests sat down under the chairmanship of Dr. E. W. G. Masterman. Amongst the visitors were Sir Arthur Newsholme, Sir William Barber, Dr. John Tate, and Dr. J. A. H. Brincker, Dr. Allen Daley, and Dr. Letitia Fairfield, representing the headquarters medical staff of the London County Council. Sir Arthur Newsholme responded to the toast of "The Visitors."

International Congress for Light.

The Congrès International de la Lumière will hold its second meeting from August 15th to 18th, 1932, at Copenhagen, under the presidency of Dr. A. Reyn. Its purpose is to consider biological and biophysical research on light and light treatment. Any doctor or physicist may become a member of the congress. The preliminary programme may be had from the secretary-general, Dr. A. Kissmeyer, Finsens Lysinstitut, Copenhagen.

National Council for Mental Hygiene.

The second biennial conference on mental health will be held at the Central Hall, Westminster, from May 27th to 29th. The subject of discussion will be the human factor as it affects international problems, crime, industry, the social services, and education. The medical speakers will include Sir Hubert Bond, Mr. C. J. Bond, Dr. H. Crichton-Miller, Lieut.-Colonel J. R. Lord, Sir David Munro, Dr. W. A. Potts, and Dr. F. C. Shrubsall.

Paying Patients.

The scheme for paying patients at Sunderland Royal Infirmary has been so successful that it is to be extended. In future the scheme will be open to single persons with one or more dependents wholly maintained by them and married couples without children under 16, up to £100 per annum; widows and widowers with a child or children under 16, up to £400 per annum; married couples with a child or children under 16, up to £500 per annum. By paying 30*s.* per year, either half-yearly or yearly—and in the case of single persons between 16 and 21 years in receipt of less than £100 per annum, 20*s.* per year—those who join the scheme together with dependants under the age of 16 years will be entitled, after six months from payment of the first premium, to free hospital treatment, including physicians' and surgeons' services, in the private wards of the Infirmary.—A proposal to provide pay-beds in the Liverpool Maternity Hospital is under consideration.

A Guild of Gratitude.

When the Royal Eye Hospital, Waterloo-road, S.E., was in a serious financial position some years ago the patients formed themselves into a Guild of Gratitude to raise money for its assistance. At the annual meeting of the guild recently it was reported that during the past 12 months the membership had increased from 16,000 to over 22,000, and that £995 was subscribed, making a total from the beginning of £3605. More than £75 has been given in farthings.

Violet Melchett Infant Welfare Centre.

The Queen last week opened the Violet Melchett Infant Welfare Centre in Wellington-street, Chelsea, founded by the late Lord Melchett, who bought the site and provided £43,000 for the erection of the model building. The centre at present stands alone in its features and is the largest benefaction of its kind yet made in England. The building comprises a day nursery accommodating 50, where children may be left for a shilling a day, a mothercraft training home, and an infant welfare centre. The central hall is used for welfare consultations, and the staff consists of matron, sister, three staff nurses, and 13 pupil nurses.

Manfield Orthopædic Hospital.

The report for 1930 of this Northampton hospital states that the institution has constantly been full to overflowing, the whole of its 128 beds being always occupied. During the year 243 patients were admitted, and 1308 persons attended the out-patient clinics. When the hospital was founded in 1925 there were 358 cripples on the register of the Northampton and County Crippled Children's Fund. Since then, 1284 new cases have been entered, and at the end of 1930 there were 1212 patients on the clinic registers. There is no adequate accommodation for dealing with an epidemic, and an isolation ward is also needed so that cases of infantile paralysis can be admitted in the acute infectious stage.

Enlargement of Nottingham General Hospital.

Lord Moynihan last week opened a new children's ward and a new theatre which have been added to this institution, at the cost of Mr. W. G. Player and Sir Louis Pearson respectively. Lord Moynihan, who made a vigorous defence of the voluntary hospitals which, he said, were creating more than 1000 new beds every year and were rather more than paying their way, expressed a strong desire for the addition of a medical school to the hospital.

Mental After-Care Association.

The annual meeting of this association was held in London on March 25th, with Lord Wakefield, the President, in the chair. Dr. Reginald Worth was elected chairman of the Council in the place of Sir Maurice Craig, who has resigned. In presenting the annual report Dr. Worth stated that the council was anxious to enlarge the work of the association by widening its activities until after-care work is established in connexion with every mental hospital in the kingdom. Already work is done in direct coöperation with one hundred mental hospitals, which represent more than half the mental hospitals in England and Wales. During the past year 410 patients were referred to the association for early treatment, in the preceding year the number was 161. Cottage homes are provided for both early care and after cases, and assistance is also given in re-establishing recovered patients in ordinary life, finding suitable occupation for them, helping them with outfits, tools, and money until they can be set upon their feet again as useful members of society.

Royal Interest in Hospitals.

On Tuesday, last week, the Duchess of York opened a new ward, named after Princess Elizabeth, in the Queen's Hospital for Children, Hackney-road, Bethnal Green. Accommodation is provided for 26 children, and it is now, for the first time, possible to segregate children under the age of 5; rooms have been provided for the reception of three nursing mothers. The ward has been built by a grant of nearly £9000 from the balance of the Children's Jewel Fund of £60,000 raised by gifts of jewellery to relieve the sufferings of children during the war. The largest contribution to that fund was a string of pearls from the Duchess of Marlborough, which realised £8000, and the smallest, a coral button which was sold for twopence. On Thursday the Duke and Duchess of York visited the Lancashire and Cheshire Tuberculosis Colony at Barrowmore Hall, near Chester, and the Duchess opened the King George V. Thanksgiving Block at the Chester Royal Infirmary. The new building contains a pathological department and a suite of three theatres. On the same day Princess Mary opened a new children's ward at Durham County Hospital. When the Princess was married she handed over £1145, the bulk of the wedding present from the city of Durham, towards the provision of a children's ward.

Victoria Park Hospital.

At the annual meeting last week of the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, it was stated that the expenditure—£36,220—exceeded the income by nearly £1500, and that as the investment income is little more than £2000, constant efforts are needed to avoid deficiencies. The convalescent home at Saunderton has had to remain closed for the last five years, and the governors have consequently felt impelled to take steps to sell it.

Vacancies

For further information refer to the advertisement columns.

Ashton-under-Lyne District Infirmary.—H.S. At rate of £150.

Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.

Bedford County Hospital.—H.S. At rate of £175.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.P. and H.S. Each at rate of £100.

Birkenhead General Hospital.—H.P. £100.

Birmingham City Babies' Hosp.—Jun. Res. M.O. At rate of £100.

Birmingham City Maternity and Child Welfare Dept.—Three Temp. M.O.'s. £10 per week.

Birmingham, Ear and Throat Hospital, Edmund-street.—H.S. for Out-patient Dept. At rate of £150.

Birmingham General Hospital.—Two Res. Anæsthetists. Eac £120. Three H.S.'s. Each £70.

Birmingham, Selly Oak Hospital.—Res. Physician. £550.

Bradford Children's Hospital.—H.S., and H.P. Each £120.

Brighton, New Sussex Hosp. for Women and Children.—H.P., H.S. Each at rate of £50. Also Hon. Asst. Ophth. Surg.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Bristol, Brentry Colony for Mental Defectives, Westbury-on-Trym Res. Med. Supt. £650.

Bristol General Hospital.—Sen. Res. M.O. £200.

Bristol University.—Lectureship in Physiology. £300–£400.

Bury Infirmary, Lancs.—H.S. to Special Depts. At rate of £200.

Bury St. Edmund's, West Suffolk General Hospital.—H.S. £180.

Chester Royal Infirmary.—H.S. £150.

Ealing Borough, Maternity and Child Welfare Services.—Asst. M.O. £450.

Gloucester, Gloucestershire Royal Infirmary, &c.—Res. Surg. O., and 1st H.S. At rate of £200 and £150 respectively.

Hampstead General and North-West London Hospital, Haverstock hill, N.W.—H.S. At rate of £100.

Harrogate Royal Bath Hospital, &c.—H.P. At rate of £156.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. At rate of £50.

Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.

Ilford Borough Council.—Asst. School Dental Surgeon £450.

Kincardine, County of.—Deputy M.O.H. £600.

Leamington Spa, Warneford General Hospital.—Res. H.P. £165.

Liverpool, Royal Children's Hospital.—Res. H.S. At rate of £100.

Liverpool Royal Infirmary.—H.S. to Orthopædic Dept. £60.

Liverpool Stanley Hospital.—H.P. and H.S. Each £100.

London Jewish Hospital, Stepney-green, E.—Hon. Asst. P.

Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophthalmologist. £250.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square, All Saints.—Non Res. H.S. At rate of £150.

Middlesex C.C.—District M.O. £80. Also Public Vaccinator.

Newark General Hospital.—Res. H.S. £175.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.

Norwood and District Cottage Hospital.—Hon. Medical Officer to X Ray, &c., Dept.

Nottingham General Hospital.—H.S. At rate of £150.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Oxford, Warneford Mental Hospital.—Asst. M.O. £300.

Plymouth, South Devon and E. Cornwall Hospital.—H.S. At rate of £100.

Poplar Hospital for Accidents, East India Dock-road, E.—Sen. Res. O. £200.

Radium Institute, Riding House-street, W.—Res. Surg. Reg. At rate of £250.

Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.

Rochdale Infirmary and Dispensary.—Jun. H.S. £200.

Rotherham Hospital.—Cas. H.S. £120. Hon. Surgeon to Ear, Nose and Throat Dept. Also Hon. Dental Surgeon to Out-patients' Depts.

Royal Chest Hospital, City-road, E.C.—Out-patient M.O. At rate of £100.

Salford City Infectious Diseases Hosp.—Jun. Asst. Res. M.O. £200.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

St. Mary's Hospital for Women and Children, Plaistow, E.—Asst Res. M.O. At rate of £120.

Scarborough Hospital and Dispensary.—Two H.S.'s. Each £175

Shanghai Municipal Council—Public Health Dept.—Asst Pathologist. 650 Tls per mensem.

Staffordshire General Infirmary.—H.P. £150.

Swansea General and Eye Hospital.—Cas. O.

University College Hospital, W.C.—Hon. Clin. Asst.

University College Hospital Medical School, University-street W.C.—Beit Memorial Fellowship for Medical Research £400.

Wakefield, Clayton Hospital.—2 H.S.'s. Each at rate of £200.

Wallasey Victoria Central Hospital.—Jun. H.S. At rate of £100.

Walsall General Hospital.—H.S. At rate of £150.

Willesden General Hospital, N.W.—Hon. Clin. Assts. Also H.P At rate of £100.

NOTES, COMMENTS, AND ABSTRACTS

TREATMENT OF RHEUMATOID ARTHRITIS.*

By A. H. Douthwaite, M.D., F.R.C.P. Lond.,
ASSISTANT PHYSICIAN TO GUY'S HOSPITAL.

Rheumatoid arthritis is a disease largely confined to women of child-bearing age, and it offers certain clinical features which render its recognition a matter of no great difficulty. For convenience it may be regarded as presenting three stages of development. In the first, joint involvement is trivial or even absent, morbid manifestations emerging as it were almost insensibly from the diathetic background of constitutional deviations from the normal. Thus we find that in childhood the patients have suffered from such disorders as urticaria, recurrent "bilious" attacks, and undue fatigue after exertion, and have, nevertheless, been mentally unusually alert and often regarded as "highly strung." After some debilitating illness, such as influenza, the first signs of rheumatoid arthritis appear, and are usually evanescent and composed of fleeting pains in the limb muscles. The peripheral circulation, always sluggish, becomes more so, producing cold extremities on which erratic sweating occurs. The main signs at this stage are of muscular rheumatism, stiffness in the morning—passing off as the limbs are exercised—tenderness of the muscle bellies, and possibly slight swelling of the finger joints in damp weather.

Investigation reveals an abnormally low blood pressure and an unstable pulse-rate; patchy pigmentation of an otherwise waxy-coloured skin; clammy, cold hands, and blue fingers; visceroptosis and constipation; exaggerated tendon reflexes and twitchings and wasting of the limb muscles. The patient, who has always been of spare build, now notices a progressive loss of weight, and the general appearance of ill-health is always very striking, forming a marked contrast to that of the osteo-arthritic. Special investigations demonstrate a raised basal metabolic-rate and a lowered sugar-tolerance which, in conjunction with the skin, cardiovascular, and nervous changes, suggest that hyperactivity of the thyroid plays an important part in the production of symptoms.

Recently, the discovery by Oriel of a proteose in the urine of these patients, often associated with the presence of large numbers of late-lactose-fermenting bacilli in the fæces, has brought us a stage further in understanding this complex subject. The importance of the urinary proteose lies in the fact that when introduced into the skin of the patient in dilutions of one in a million, it may give rise to intense local reaction in the form of a wheal, and even to a general reaction, as evidenced by sudden swelling and pain of the smaller joints of the body. Considering the infinitesimally small amount of substance which produces such widespread changes, it is clear that one cannot be dealing with an example of non-specific protein shock. In point of fact Oriel's proteose is highly specific, producing *a reaction only* in the patient from whom it has been recovered. Urine containing the proteose gives rise to the so-called "ether reaction." The test consists of the addition of 25 per cent. sulphuric acid to an equal amount of urine, followed by a little ether. The whole is shaken up and allowed to stand. The uppermost, etheric layer *may* develop in its deeper portions a waxy consistency which, if well marked, is taken as a sign of positive reaction.

In various diseases, notably migraine and asthma, proteose is also obtainable and produces local and constitutional reactions according to the nature of the underlying disease. Proteose from an asthmatic will have no effect upon a case of rheumatoid arthritis, and vice versa. It probably represents a most important link between the exogenous morbid agent—e.g., the bacterium or foreign protein, and the ultimate reaction of the bodily tissues which give rise to the clinical signs of disease. It is, in fact, probably produced as a result of liver damage initiated by the exogenous agent. This being so, it is understandable that a disease with the uniform characteristics of rheumatoid arthritis may apparently be caused by diverse agencies, in one case focal sepsis appearing as an ætiological factor, in another bacterial influence being absent but endocrine derangements prominent; yet in both, the above-mentioned metabolic abnormalities are precisely similar. Slight differences in constitution of these proteose bodies would then account for different manifestations of disease, the constitutional tendencies of the individual, of course, playing an equally important rôle.

The vexed question of the part which focal sepsis plays in the production of rheumatoid arthritis is no longer difficult to answer. It may be accepted that the disease is never directly caused by microbial invasion in the sense that we find it in infective arthritis, nevertheless in a proportion of cases bacteria or their toxins may act as a flame applied to a fuse, and thus lead indirectly to an explosion which is represented by the acute form of rheumatoid arthritis. Other agencies—e.g., exhaustion, protein sensitiveness and so on, may, however, act in like manner in the absence of microbial activity.

Treatment of First Stage.

In the initial examination septic foci will be looked *for and subsequently removed, but when doubt exists* of the presence of focal infection the wisest plan is to leave the area alone. An incalculable amount of harm has been done by wholesale dental extractions on insufficient grounds for early gingivitis or supposed apical infection. Rheumatoid arthritis is a general disease, and one, therefore, in which healthy gums are *no more likely to be found than is a healthy skin.* Recovery is commonly accompanied by complete disappearance of early oral disease.

Most forms of physical treatment aim at producing cutaneous vaso-dilatation, generalised sweating, and pyrexia. An improvement in the peripheral circulation is always followed by diminution of the unhealthy *state of the skin and* recession of arthritis, muscular stiffness, and pain. Theoretically, therefore, the different types of thermal treatment should be equally efficacious. This is not, however, the case. Furthermore, in practice one has constantly to bear in mind the patient's difficulties, financial or otherwise, in carrying out special treatment at spas or similar institutions. Radiant heat is exhausting and produces only the most transient relief of symptoms.

Foam baths certainly result in vaso-dilatation, profuse sweating, and diminution of stiffness. The patient is placed in an ordinary bath containing about six inches in depth of hot water to which a special solution of saponin is added. Air is pumped through the water, producing an enormous amount of foam which completely envelops the patient. The temperature of the water is about 104° F., but, owing to the large amount of air in the foam, heat loss is very slow. The stimulating effect of the rising air bubbles accounts in part for the absence of exhaustion in the treatment. The effect of hot paraffin wax baths is very similar. The patient is washed over with wax at 60° C., which solidifies at 45° C., and thus *encloses the body in an* envelope. Several layers are applied and allowed to remain for half an hour. Thereafter they are peeled off in one sheet, the profuse sweat is removed by a hot-water douche, and the patient subjected to general massage and muscle kneading.

The simplest and most valuable form of thermal treatment consists of the old-fashioned hot wet pack, that the lovebirds were the original source of infection. A circular issued by the U.S. Public Health Services states that psittacosis is one of the most highly contagious diseases known. In the outbreak of 1929–30 there were 74 places of infection, which gave rise to 169 cases with 33 deaths, not including 16 laboratory infections with two deaths, or 12 probable cases on two merchant ships entering U.S. ports. Limited importation of parrots under supervision is now permitted, proper care and sanitation of the birds during shipment being prescribed, and a period of observation under quarantine at the port of arrival.

* The substance of an address to the Wimbledon Medical Society.

THE PHYSICIAN'S HANDS.

A CORRESPONDENT comments upon the feelings of the patient as the hands of doctor or nurse approach him, wondering whether they are to be warm with the comfort of healing or like slabs of ice. Much goes with the magic of the hand. If it be just right for the fevered brow, will it be right in percussing the chest or exploring the more sensitive surface of the abdomen? Fortunate the doctor who can use his hands in all such manipulations so that the patient never apprehends the coming ordeal; for there is much more than the surface temperature of the hands which determines the impressions of contact. Be they ever so hygienic and right in warmth, yet if they lack that extra touch of capacity they fail; that feeling of warm firmness, not devoid of gentleness, brings to the mind of the patient a sense of relief to be in such hands. There are at least four kinds of hands easily recognisable in this matter of comfort. The one already mentioned which is just right; the hand which is hygienic and warm, though devastatingly damp; a third which is dry and harsh in texture, comforting as an east wind; lastly, the hand that to the owner is never cold, to the patient never otherwise. The surgeon is remembered by the result of the operation; if it succeed, all is well; if it fail all else is forgotten be the hands ever so right. The physician has to stand another test, and it is possible that many a "grateful patient" has as big a measure of gratitude for hands as for head. But we fear the cold hand can never be changed until we have learned how to regulate the peripheral circulation.

REPORT OF MENTAL WELFARE CONFERENCE.

THE Central Association for Mental Welfare, which held an important conference at the B.M.A. House from Dec. 11th to 13th last, has issued a report of the conference which may be obtained for 3*s.* 6*d.* from the hon. secretary, Miss Evelyn Fox, at 24, Buckingham Palace-road, London, S.W. 1. The conference was the more valuable as the formal papers presented to the five sessions were taken as read, the authors merely calling attention to particular points which they desired to bring out, and leaving time for full and useful discussion. The conference covered a wide field of mental welfare.

MILK CONSUMED IN NEW YORK.

IN the course of a health survey conducted in New York City last September by nurses of the Department of Health for the purpose of supplying information desired by the White House Conference on Child Health, an inquiry was made as to the amount of milk used in the different families visited. The survey covered about 14,000 families in various parts of the city, evenly distributed among the socio-economic groups. The average consumption of milk per head was found to be 0·98 pint per day, compared with 0·55 pint in 1910–14 and 0·80 pint in 1926. The number of children is known, but not the amount of milk they consumed. Assuming however, as the Health Commissioner thinks reasonable, that the adult members of the families consumed each not over half a pint, the average per child of the lowest economic group works out at 1·07 pints, and in the other groups from below upward 1·48, 1·42, 1·60, and 1·61 pints. A continuance of the educational campaign will, the Commissioner remarks, gradually raise this to the quart per child advocated by all authorities in child health.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

WEST KENT MEDICO-CHIRURGICAL SOCIETY, Miller General Hospital, Greenwich, S.E.
FRIDAY, April 10th.—8.45 P.M., Mr. E. A. Lindsay: Common Disabilities of the Feet and their Treatment.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, Cavendish-square, W.
THURSDAY, April 9th.—8.30 P.M., Discussion on Anorexia Nervosa opened by Dr. Langdon Brown and Dr. Crookshank.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.
FRIDAY, April 10th.—7.30 P.M. (at the De Vere Hotel, Kensington), Dinner Meeting followed by Cinematographic Demonstrations illustration Blood Transfusion, the Mechanism of the Normal Heart and the Sufficiency and Insufficiency of the Mitral Valve.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.
FRIDAY, April 10th.—4 P.M., Mr. Nicol Rankin: Earache.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.
WEDNESDAY, April 8th.—4 P.M., Dr. H. V. Morlock.

ANCOATS HOSPITAL, Manchester.
THURSDAY, April 9th.—11 A.M., Mr. P. G. McEvedy: Clinical Demonstration. 4.15 P.M., Mr. E. E. Hughes: Cystitis.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.
FRIDAY, April 10th.—3.30 P.M., Mr. Hay: Visual Disturbance of Cardiovascular Disease.

Appointments

JARRETT, R. F., F.R.F.P.S.G., has been appointed Medical Superintendent, Kent County Institution for Mental Defectives, Leybourn Grange, near Maidstone.

WALLACE, W. H. S., L.R.C.P. Lond., M.R.C.S., Assistant Resident Medical Officer, City of London Maternity Hospital.

Queen Charlotte's Maternity Hospital: HUNT, T. C., D.M. Oxf., M.R.C.P. Lond., Hon. Asst. Physician. BELL, A. C. H., M.B., B.S. Lond., F.R.C.S. Eng., Registrar.

Certifying Surgeons under the Factory and Workshop Acts: PEILL, S. G., M.B., Ch.B. Edin. (Leyburn, York); ROLFE, D. A., L.R.C.P. Lond., M.R.C.S. (Llangennech, Carmarthen).

Births, Marriages, and Deaths

BIRTHS.

MCQUADE.—On March 26th, at Harcourts, Chertsey, the wife of Dr. C. E. McQuade, of a daughter.

DEATHS.

ARNOTT.—On March 27th, at The Precinct, Rochester, Henry Arnott, F.R.C.S., Honorary Canon of Rochester, in his 89th year.

BARNETT.—On March 27th, at the Royal National Orthopædic Hospital, Country Branch, Brockley Hill, Stanmore, Middlesex, J. Binford Barnett, F.R.C.S., aged 38.

ROBINSON.—On March 25th, of pneumonia, Florence Maud Robinson, M.B., Ch.B., Balshagray-avenue, Glasgow.

STACK.—On March 26th, at Tankerton, Kent, Lieut.-Colonel Edward Churchill Stack, F.R.C.S.I., R.A.M.C., T.D., retired.

WOOD-WHITE.—On March 22nd, at Handsworth, Birmingham, Edward William Wood-White, B.A., M.D., in his 76th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

BIRMINGHAM GENERAL DISPENSARY.—The Lord Mayor of Birmingham last week opened a new branch of this dispensary in the suburb of Selly Oak. This makes the ninth branch in the more densely populated areas of the city. In 1793, the first year of the dispensary's existence, it treated 280 patients; in 1930 it treated 76,632.

ADDRESSES AND ORIGINAL ARTICLES

DELUSIONS.*

BY HENRY YELLOWLEES, M.D. GLASG.,
F.R.C.P. EDIN., M.R.C.P. LOND.,
PHYSICIAN AND LECTURER IN PSYCHOLOGICAL MEDICINE TO
ST. THOMAS'S HOSPITAL.

TWO phrases connected with mental disorder appear in the public press with such painful frequency that one can hardly search a daily paper without coming across one or other. One is, "he was found to be suffering from delusions," and the other—generally in the report of an inquest—is, "his doctor had been treating him for depression." The sad thing is that nine times out of ten the first phrase is meaningless and the second one untrue. It is the first phrase which is our present concern.

For the moment, let us accept, without troubling over fine distinctions and special cases, the simple definition that a delusion is a false belief which is not shaken by argument, or even by demonstration of its falsity. A little reflection will convince anyone that practically his entire circle of acquaintances "suffers" in this way, and most of us will agree that few, except ourselves, are entirely free from irrational beliefs. On the other hand, our friends do not seem to be particularly the worse of their irrational beliefs, and only rarely do we feel disposed to say that even the most bigoted of them "suffers from delusions" in the newspaper sense.

The popular phrase is, of course, an attempt at a clinical, *comprehensive, and non-actionable definition* of "insanity," and there seem to be two reasons why it should have become the accepted method of conveying this sinister idea. Firstly, there is the dearly cherished public belief that there can be no insanity without delusions, that insanity simply consists in "having delusions," and that the type and model of all mental patients is that legendary figure, the man who believed himself to be a poached egg. Secondly, there is the universally accepted view that "delusions" are the final and convincing *proof* of insanity.

Delusions, if we adhere to the rough general definition with which we began, may certainly occur in almost every type of mental disorder, but while in some mental disorders they are of profound importance, being indeed at the very root of the illness, in many others they are merely incidents, often of the most trifling significance, and sometimes quite unworthy of the weighty name "delusion" at all. Very often, indeed, a "delusion" would never receive such a title but for the fact that an insane man uttered it. When our friend who is spending a seaside holiday with us announces at breakfast with a resounding slap on our back—or his own chest—that he could eat an ox, or push over a house, we accept his remarks as merely picturesque expressions of a sense of well-being. Even when Sir Galahad informs us that his strength is as the strength of ten, giving us his reasons for his belief and appending a summary of his exploits, we regard his statement as figurative, and murmur "poetic licence." But let Mr. Smith, next door, merely state that he believes himself to be the strongest man in the country or the best billiards player in Europe (modest claims compared with those we have mentioned), and he has given adequate grounds for someone to certify him, which is bad, and probably to add the remark that he is a case of "delusional insanity," which is very much worse.

Why should it be that what we regard in our friend as just his fun, and in Sir Galahad as merely getting the poetry out of his system, should be regarded in Mr. Smith as manifestation and proof of "insanity"? The various answers to that question illustrate the *absurdity of attaching any importance whatever to* a "delusion" away from its context—that is to say, apart from a knowledge of the mental state of the person who expressed it, and of the circumstances in which he did so. It may be helpful, therefore, to consider a few common types of delusion, noting their *differing* modes of origin and the tremendous variations in their significance.

Types of Delusion.

(1) "Delusions" may be merely the expression of a mood or emotional state. This has been illustrated above, and many other examples might be given, such as that of the depressed and disappointed man who states his belief that everyone is against him, or that he does not care if he were to die to-morrow, or that for two pins he would resign his post and go to Australia. Such beliefs are generally fleeting and are, of course, perfectly consistent with "sanity," though they may sometimes exist for considerable periods of time and, while they exist, are certainly impervious to argument.

(2) Delusions may be the *result* of an emotional state, in a far more serious and important way than the above. It is not in human nature to experience an emotional state of any duration or intensity without immediately searching for some "cause" or "explanation" of it. Nobody has yet been found to admit that his own emotional reactions are disordered or disproportionate, or even that they are provoked by causes of which he is not fully aware. Nothing short of a general anæsthetic, an attack of acute confusion, or a state of really profound dementia will prevent a man from explaining his actions and, even more, his feelings to himself on *strictly logical grounds to his own entire satisfaction.* As such grounds are more often than not conspicuous by their absence, we are all from time to time in the position of the lady who, having pointed out a cow to her four-year-old son, received in answer the one word: "Why?"

The whole essence of melancholic depression, for example, is that it is out of all proportion to any ascertainable cause. Were it not, it would not be an abnormal emotional state and would not be melancholia at all. This state of things, however, presents no difficulties to the patient, whose thoughts, could they be analysed and clarified, must run somewhat on these lines: "I am very miserable. There must be a cause for it, which I must find out. Good people are happy. I've always been taught so. I am unhappy, therefore I am not good. I am desperately miserable, therefore I must have been terribly wicked."

At this stage the patient tends to explore his entire past life in the desperate attempt to find something therein wicked enough to explain his present misery to himself. There is nothing so pathetic in all mental medicine as to hear some patient of blameless life faithfully rehearsing every detail of some childish misdemeanour of half a century ago in the hope of finding at least an explanation, if not an alleviation, of his torturing distress. But few, if any, patients are satisfied with the facts they bring to light in this way. An overwhelming distress demands a correspondingly stupendous "cause," and the patient—because he cannot help it—invents delusions on a scale appropriate to his misery. He has committed unpardonable or unnatural sin, he has robbed and swindled all his friends, and he is about to be put to a cruel death as a punishment both for his own sins and for those of a lost world.

---

* An address to the St. Thomas's Medical and Physical Society.

Now by any ordinary definition these are certainly delusions, but in spite of their apparent prominence, they are, in fact, of extremely little importance in the case and its treatment. The patient is not "suffering from delusions." He is suffering from depression, and the secondary intellectual disorder is merely a reaction to the primary emotional one. One interesting proof of this, among many, is that if a melancholic patient is wisely questioned about some one of his "delusions," he will often say: "I know I committed *that* crime, not so much because I remember doing it, but because I *feel* that I must have done it." Such delusions call neither for argument nor for direct treatment. They are the products of the emotional disorder, and apart from it, they have no depth of earth. As soon as the emotional balance is restored, they will certainly vanish away, because there is nothing left to produce or to sustain them.

(3) Delusions may occur as a consequence of hallucinations. Before discussing this point fully we may dismiss at once one sense in which it is true in a superficial and unimportant way. Any patient who is in acute confusion or intense excitement is liable to utter wild or rambling phrases which are no doubt prompted by the hallucinations he is experiencing. That the incoherencies and absurdities uttered by an acutely ill patient, wholly out of touch with his environment, should be seriously described on many a certificate as "delusions" simply shows how meaningless that word, as generally used, has become.

But the relation of delusions to hallucinations is a much more important and complicated matter than the above. An hallucination is generally defined as a sense perception arising in the absence of any external stimulus, whereas a delusion, whatever else it may be, is a question of *belief*. But the borderline between experiencing a perception and "believing" in it is so exceedingly fine as to be practically non-existent. To hear church bells is to believe that one hears church bells, and one can hardly have seen a green dragon if one does not believe that one has done so. Seeing, in fact, is believing. An hallucination being a perception without an object, it follows that belief in it is a mistaken belief—that is, a delusion. Hence delusions are the immediate and inevitable outcome of hallucinations.

This thoroughly unsatisfying view of the problem held the field unchallenged for many years, and, indeed, is still to be found in several of the text-books. It was not usually pushed to its conclusions as above, but expressed more as follows:—

A patient experiences, say, an hallucination of taste which persists unaltered for days and weeks. At first he reacts as any normal person would do by making light of it, regarding it as an accident, suspecting that his teeth require attention, that his digestion may be at fault, and so on. The constant recurrence, however, of the inexplicable metallic taste in his mouth at every meal drives him inevitably sooner or later to the conviction that the fault must lie not in himself but in the food. The obvious logical steps of change of diet, of cook, and of residence now follow, and, as they successively prove ineffective, the patient's weakened and overwhelmed judgment arrives at the only possible explanation which remains—namely, that his food is being systematically tampered with. From this point an almost infinite number of sinister deductions are inevitable, and are woven in due time into an elaborate delusional system. The nature and source of the harmful material have to be conceived and its lack of fatal effect explained. His tormentor has to be identified and may have to be credited with the powers of invisibility and omnipresence, while in addition some reasons must be adduced for his apparently "motiveless malignity." It will be remembered that in his portrayal of Iago, Shakespeare has difficulty in this last respect, and the reasons he gives are far from convincing, but the problem which taxed the genius presents no difficulties to the madman.

We have thus a marvellously complete and logical system of beliefs proceeding naturally and inevitably from one false premise, which in its turn arose from a mistaken sense-impression.

Now all this is correct enough as far as it goes, and no doubt delusions may be considered to arise from hallucinations in this way. In such cases as that indicated above, however, the delusional system is the very essence of the disorder, and the above view of its origin, though plausible, is superficial. Not only does it make the delusions quite definitely secondary, which they are not, but it leaves entirely unexplained the hallucinations from which the delusions are said to arise and with which they are so intimately connected.

It seems much more probable that both hallucinations and delusions have a common origin and are best regarded as different but allied manifestations of the same deep disorder of mental function. Before discussing this point of view we must note two further ways in which delusions may occur. One has been hinted at, and indeed illustrated, by what has just been said, but is put separately for the sake of completeness.

(4) Delusions may arise as a consequence of previously existing delusions.

In any delusional system it is only the first or initial delusions which are of real clinical importance. The others, as has been illustrated above, tend to follow as natural consequences. They are merely the supports which the patient produces to sustain the original idea and to give it an appearance of reasonableness and consistency. Just as a single isolated lie generally begets a brood of secondary ones, if detection is to be avoided, so does a delusion produce a crop of subsidiary delusions whose function is to protect their parent by anticipating and explaining away any rebutting evidence that might be offered.

The amateur liar weaves a proverbially tangled web, but his inventions are crude indeed compared with the rationalisations of the delusional patient. The life of the asylum "Queen," for example, is clearly one long series of inconsistencies and incongruities, for each of which she must be prepared to give—and does, in fact, give—a "reason" at a moment's notice. If the man who believed himself to be a poached egg had ever existed, one would think that the energy and ingenuity he must have devoted daily to explaining and rationalising his position, would in themselves have been sufficient to convince him of his error. A patient did once exist who believed himself to be the great Napoleon. One day he carelessly announced himself to be the Duke of Wellington, and when reminded that yesterday he was Napoleon, replied instantly: "Yes, but that was by another mother!" While it would be true enough, in a sense, to say that this patient "suffered from the delusion that he had had two mothers," such a statement could not possibly be made by anyone with the slightest insight into the mechanism of delusion formation.

(5) Delusions may arise as the result of toxæmia or infection, that is, from purely physiogenic causes. A brief study of the toxic psychoses and of general paralysis makes this perfectly clear. In general paralysis for example, we listen to the patient's stream of fantastic delusions and reflect that their primarily responsible cause is the invasion of his central nervous system by the micro-organism of syphilis.

For any account of the actual modus operandi of such toxic and infective factors we must look to the physiologist and histologist. We have reached that dangerous and unexplored no-man's-land lying between physio- and psycho-pathology, which is the limit of safety for any discussion starting from a psychological point of view. We may, perhaps, remember the old conception of physiological levels, and suggest that by an actual poisoning and destructive process, inhibitory machinery is paralysed and "lower" levels allowed free play. With that said we must retire in good order, wondering if knowledge of brain physiology has really advanced since the day of Hughlings Jackson. We may, however, make one very interesting reflection. In all the states accompanied by delusions in which physical factors have to be admitted or postulated, the delusions are never the essence of the disorder, but are invariably of the comparatively unimportant and, as it were, "accidental" types discussed earlier in this lecture. Even in general paralysis this can be shown to be true.

Delusions are by no means always a prominent feature of that disease. Quite often they are few in number and occasionally they are entirely absent. At their worst they are fleeting, variable, and unsystematised. Far from "suffering from" them, the patient tends to play with them, and their influence on his conduct as a whole—apart from isolated outbursts—is slight. His attitude towards them is in striking contrast to that of the patient who really "suffers from" delusions, which affect his entire mental life. There are few things in psychiatry more interesting and instructive than to compare a very "delusional" general paralytic with a truly paranoid patient. A serious disagreement with the latter may bring in its train any amount and variety of trouble even up to an attempt at homicide on his part, but in the case of the general paralytic it is not difficult with ordinary tact to "call his great truth a lie," and be rewarded for one's courage with a cheque (not negotiable) for half a million.

(6) The only delusions which, by virtue of their fixity, their chronicity, and their grip of the entire personality and outlook of the patient, really merit the name, arise in none of the above ways. They demand, first of all, a certain soil in which alone they can develop. This soil is that mysterious thing commonly called the "paranoid temperament" or "the shut-in personality," about which only a few words may be said in passing.

It may exist in many and varying degrees. It is often and largely, but certainly not always or entirely, the result of postnatal influences and environment. It seems, as far as we know, that however unfavourable these influences may be, there is an inherent something in the fertilised ovum, the presence or absence of which determines the extent to which they shall prevail. The chief early manifestations of the paranoid temperament are moodiness, shyness, aloofness, unsociability, dreaminess, and unreliability. These are signs of the withdrawal from reality which is the hallmark of this state. The natural tendency of the "shut-in personality" is towards evasion of the issue on every possible occasion, and its victim becomes shut off from effective contact with his environment by a fence of his own constructing. It is in such soil that true delusions will flourish.

Origin and Growth of Delusions.

As regards the question of their actual inception, one supposes that the seeds of a delusion are sown when a patient has thrust upon him some idea, experience, situation, or some aspect of himself which, by virtue of its own significance or importance, demands more frank directness of treatment than the patient has the power to give. His limited ability to deal with reality, that is to say, is simply overtaxed, and the idea, thus become intolerable, has to be dealt with by some of the reality-avoiding devices we are about to discuss. The breaking-point depends upon the degree in which he possesses the paranoid temperament and upon the nature and importance of the reality with which he has to deal.

It remains to consider the growth of a delusion when such a situation has arisen. It is obvious that the person who avoids reality is the person—when one comes to think of it, the only person—who is likely to deny reality by believing the thing which is not. "Having delusions," in fact, may be regarded as a characteristic manifestation and, sooner or later, an almost necessary consequence, of the paranoid temperament in any great degree.

One can conceive of avoidance of reality being achieved and maintained in two distinct ways. On the one hand, the individual may be pictured as shutting his eyes to the world of reality which is both around and within him, and withdrawing into a private, unreal, dreamy world of his own creation. On the other hand, we may imagine him as more or less standing his ground but hurling realities away from him whenever they show signs of breaking through his defences. We can avoid the company of an intruder either by running away ourselves or else by making him do so. Either plan may be preferable, depending on circumstances.

Both methods are constantly adopted by the mind in dealing with intolerable ideas. The name of the one is phantasy, and the name of the other is projection. We owe the elucidation of these mechanisms and the demonstration of their vital importance in psychopathology to the genius of Freud. Whatever may be said of his work or his views, he was certainly the first to offer even a conceivable hypothesis of the formation of delusions, and intelligent discussion of the subject is impossible without the constant use of his conceptions and his very phrases.

As phantasy plays a considerable part in the mental life of most of us, little explanation of it will be needed for our present purpose. We all build so many dream worlds of our own that it requires no great effort of imagination to conceive of a patient seeking permanent instead of momentary shelter in a lifelong daydream of his own fabrication. It is simply a question of fact versus fancy. In the world of fact he is powerless; in the world of fancy he is omnipotent. It is his constant tendency to avoid the world of fact.

Is it surprising then that he chooses the world of fancy as his real world and pays the price—divorce from reality—with a smile?

The "Queen" of the chronic mental hospital ward is simply what we have all been at moments—the central figure of a fairy tale. But her fairy tale is her own, and has become her whole life. In the life she has abandoned she was either poor, or overworked, or jilted, or friendless, or baffled, or without hope, opportunity, or outlook. Some reality was certainly an intolerable load or an insurmountable obstacle. So she followed the natural tendency of her mind, fled into her kingdom of fancy—and reality will never trouble her again. She has passed, of course, far out of hearing of logic, reason, or reproach; she "is too far off for wings of words to follow." We cannot "treat" her, we need not argue with her, and sometimes I am not very sure that we should even pity her.

Projection is a more subtle and important mechanism. It is the disowning, as it were, by the patient of some part of his personality, the realisation and acceptance of which would be intolerable. The offending idea is not admitted to consciousness, but is hurled by the patient away from himself and into his environment. But the environment in such a case acts very much as the wall against which we fling a tennis ball. The ball returns to the thrower at a different angle, and with a force proportionate to that with which it was flung. The patient who projects unacknowledged aspects of himself into his environment will surely receive them back again, and we need not be surprised if he has difficulty in dealing with the rebound.

The idea will return in a new but complementary form and will appear to have come from some part of his environment, but it is a return journey for which the environment is in no way responsible. The tennis ball rebounds from the wall because it was flung there. Action and reaction are equal and opposite. A man casts out the idea that he is deceitful and receives back the idea that others are deceiving him; he rejects the thought that he is incompetent and receives the suspicion that he is surrounded by incompetents who conspire to put him in the wrong; he stifles the voice of conscience only to have it with him throughout life as the voice of supposed calumny.

We cannot enter here on a full discussion of this profoundly interesting and very difficult mechanism. Superficial instances of its working are common enough, and a very little study of it suffices to convince one that here, at last, we have the mechanism *par excellence* of delusion formation. We must leave it at that, because in the time that remains I wish to touch on a few general points which I hope that this short study of delusional states may have suggested.

Delusions about Delusions.

In the first place, these reality-avoiding mechanisms of phantasy and projection can be illustrated a hundred times in the everyday life and conduct of every one of us, which I suppose is tantamount to saying that they are characteristic of the mind in health.

I suppose it is this fact, hastily swallowed and ill-digested, which accounts for the immortality of that cheap and inane pleasantry so beloved by lawyers, as well as by those who ought to know better: "but we are all more or less mad, are we not, doctor?" We are nothing of the sort; we have not that excuse for talking as if we were.

It is not merely a question of degree either. To say that if you and I were to seek refuge from reality in phantasy more often than we do, we should be so much nearer to a delusional psychosis, is absurd.

The psycho-analytic school give the impression that if the hysteric or obsessional case were to deal with his conflicts by projection instead of by conversion or substitution he would promptly become a case of paranoia. I do not say that they mean to give that impression, and I hope they do not, because it is a mistaken and misleading one. No overaction of the mechanism of projection can make a man a paranoiac, but a paranoiac patient, among others, will make an excessive use of that mechanism. A knowledge of it will help us to understand the structure of his delusions but will bring us no nearer to a comprehension of the strange soil in which alone they can grow—namely, the shut-in personality in which they are rooted and grounded.

It has, I hope, been realised from what has been said that a delusion is far more than a mistaken belief on a point of fact. Delusions are symptoms which are wonderfully varied in their significance. When their significance is grave—when the patient really "suffers from delusions"—they are manifestations of an abnormal, warped attitude to life and to every department of it. The man who was "mad on one subject only" was long since about to join the shadowy company of the poached-egg gentleman and the sea-serpent, but he was caught by the strong arm of the law and now he earns a dishonest livelihood as a tried and trusted legal fiction.

It is, however, to our own profession that we owe the most startling and original suggestion for the investigation of delusions. It is proposed that the patient and the doctor who alleges delusions against him, along with the witnesses which either may desire to call, should proceed to a court of law. Here the patient, represented by counsel, is to be formally accused of "having a delusion," the general procedure being the same as in a case of alleged drunkenness. If the doctor can prove that the patient expressed a mistaken belief, the patient loses his case and may be certified, but if the judge decides that the belief has not been proved to be false, then the patient wins, and, presumably, an action for damages lies against the doctor. Though such a performance might indeed go far towards reviving the spirit of Merrie England among us, yet I think that its entire lack of science, humanity, and common sense place it more fitly as a relic of the Middle Ages.

ROYAL NORTHERN HOSPITAL.—Presiding at the annual council of the governors recently, the Marquis of Northampton said that an important piece of pioneer work had been undertaken by the development of the treatment of cancer by means of activated fluorescein with encouraging and satisfactory results. Special grants for the continuance of the treatment have been made by the Cancer Committee of the Ministry of Health. Sir Howell Williams, who had given £35,000 towards the cost of a new private patients' block, has increased his gift to £47,636, the amount of the builders' contract.

PROGRESS OF CONTRIBUTORY SCHEMES.—The governors of the Royal Hospital, Wolverhampton, have decided that it is "absolutely necessary" to establish a contributory scheme, and a joint committee representing the hospital and the Eye Infirmary has been appointed to draw up a scheme for the consideration of the Hospital Saturday Committee.—Last year's subscriptions to the city of Portsmouth contributory scheme amounted to £10,342, an increase of £841.—The contributory scheme of the King Edward VII. Hospital, Windsor, now has over 27,000 members, and the amount raised last year was only a few pounds short of £11,000, an increase of more than £1200 over the previous year.—When the contributory scheme of Cheltenham Hospital was started, 16 years ago, it produced £58; in 1930 it raised £7152.

GONOCOCCAL INFECTION OF THE SEMINAL VESICLES.

By Richard S. Roper, F.R.C.S. Edin.,
FIRST ASSISTANT IN THE UROLOGICAL DEPARTMENT, KING'S COLLEGE HOSPITAL.

Having studied in 35 cadavers the difficulties encountered in catheterising the ejaculatory ducts, I find that the chief are: (1) poor visibility of the ducts; (2) yielding nature of the verumontanum; and (3) resistance to passage of a catheter along the duct even after perfect engagement in the orifice.

Even if the most perfect view of the posterior urethra be obtained it is sometimes impossible to see the ducts. The procedure was first to examine the posterior urethra and look for the openings. If these were visible an attempt was made at once to catheterise them. If they were invisible the vas was exposed and methylene-blue injected while the posterior urethra was still in view. The openings were then easily recognised by the flow of the stain. In 19 examinations the openings could not be seen before injection. The reason in 12 cases was that they were situated behind the margin of the verumontanum and faced the lateral walls of the prostatic urethra, the injected fluid squirting out at a right angle. In 16 the openings were visible most commonly rather to the side of the base of the verumontanum. Only in five cases did the openings face the observer as in the well-known "diver's helmet" variety.

It is difficult to agree with Luys,[1] who, in his recent book, maintains that the ducts are more difficult to see in the cadaver than in the living subject. The pallor of the mucous membrane and the absence of any kind of movement or of blood, are likely to be in favour of visibility in the cadaver. There is also no necessity for haste.

The ureteric openings will "stand up to" the passage of a catheter, but the soft structure of the verumontanum is easily pushed out of view of the small field in which the observer has to work, or may be perforated by the catheter. I have confirmed the observation of McCarthy[2] and Thomas[3] that the duct turns up at an angle of 45 ° at its termination. To overcome some of the difficulties of the manipulation Mr. Schranz, of the Genito-Urinary Manufacturing Company, made for me a urethroscope which he describes as follows.

> The instrument consists of a sheath 21 Charrière in circumference and nine inches long. The sheath terminates in a beak of a convenient curvature for introduction. At a distance of two inches from the distal end is a lateral opening, 9/16 of an inch long, into which projects the lamp. This opening can be occluded for easy introduction by means of an articulated obturator. In so far, the instrument differs only in its small size from the American pattern urethroscope. The internal arrangement of the telescope and catheter carrier is, however, constructed on entirely different principles. The catheter carrier lies at the bottom of the sheath—i.e., furthest away from the opening, and the telescope is on the top. With this arrangement the field of operation is left free and the catheter does not come directly in front of the objective and obstruct the view as in older models. Further, the articulated portion of the carrier, corresponding to the Albarran lever of the cystoscope, is tubular and therefore positive in action in both the up and the down movements. The latter point is of great importance when it is necessary to direct the tip of the catheter with precision, as in the present operation. The telescope is provided with a special prism which deflects the optical axis forward in such a way that the tip of the catheter appears in the centre of the field when it is in the best position for introduction into the ejaculatory duct. The optical system is designed to give unit magnification at one inch distance in air; that is, it does not magnify but only transposes the image of the object. When used in fluid the necessary magnification is present owing to the difference in density of the two media. The depth of definition is restricted and does not extend beyond one inch from the objective. The field is sufficiently wide to embrace the whole of the verumontanum and the lateral fossæ of the posterior urethra when medium distension is used.

By means of this instrument it was occasionally possible to pass a No. 3 Charrière catheter far enough into the ejaculatory duct to inject the vesicle, but the successes were so few in comparison with the attempts that the method must be looked upon as of limited use from the point of view of obtaining the contents of the vesicle or treating it by lavage. No extensive use of this instrument has yet been made on the living subject, but it is possible that the ducts could be catheterised with it in some cases.

On account of its small calibre and the precision with which a catheter or diathermy electrode can be manipulated in such a small space, this instrument is invaluable for any operative work in the posterior urethra.

In 1905 Belfield[4] stated that vasotomy was the only means of medication of the vesicles, and since that time the method has been extensively used in America and France. From a study of the literature of the subject it does not appear that cases for vasotomy have always been carefully selected, and there seems at times an inclination to use this procedure in cases which would yield to older and less drastic methods.

Anatomical Observations.

In 1668, according to Luys,[1] de Graaf demonstrated that fluid injected into the vas reached the vesicle before entering the urethra. In the more recent literature there have been many attempts to explain this phenomenon. The presence of spermatozoa in the vesicle shows that testicular secretion reaches the vesicle in the same way as injected fluid, so that there is a natural tendency for the contents of the vas to flow in this direction. Although the outer walls of the vesicle and vas are intimately fused at their junction, the opening at this point is very small, and immediately preceding it is the rather dilated ampulla. It is not unreasonable to assume that the thick muscular wall of the vas may act as a sort of pump, the contraction of which reaches its maximum effect in the ampulla. Fluid expelled with increased force through the small hole in the vas at its junction with the vesicle meets the small calibre of the ejaculatory duct and regurgitates into the large opening of the vesicle. The relative size of the openings and calibres of the parts is diagrammatically represented in Figs. 1 and 2.

At the termination of the ejaculatory duct there is a definite thickening of muscular tissue which is called by Belfield the "sphincter spermaticus," and which is believed by some to offer the necessary resistance to produce regurgitation into the vesicle. In the cadaver, fluid injected into the vas enters the vesicle just as readily as in the living subject, so that the contraction of this sphincter does not seem to have as much influence as mechanical obstruction.

The rectovesical layer of the pelvic fascia (Denonvilliers) binds the vesicles to the posterior aspect of the bladder and has abundant cellular tissue beneath it, dipping down between the coils of the vesicle, and also a large network of vessels in its meshes. Although the fascia itself is tough, there is ample room under it for the cellular tissue to swell. Jordan Lloyd[5] in 1889 described a perivesiculitis which he likened to periepididymitis, and it is possible that what he described is an inflammatory condition of this tissue. The difference in symptoms is amply accounted for by the different anatomical arrangements of the vesicle and epididymis. Whereas the vesicle is embedded in loose cellular tissue, the epididymis is enclosed in a tough non-expansile capsule. In the first instance the condition may be painless and symptomless; in the second the disease of the epididymis is obvious from the beginning. Both conditions are good examples of the predilection of the gonococcus for cellular tissue if confined in its surroundings. The vascularity of the cellular tissue is such a marked feature that it would seem to influence the clearing-up of most cases of perivesiculitis and the occurrence of rheumatism in chronic cases.

FIG. 1.

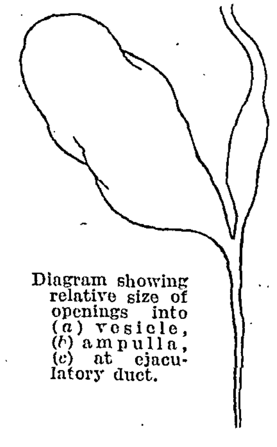

Diagram showing relative size of openings into (a) vesicle, (b) ampulla, (c) at ejaculatory duct.

DIVERTICULA.

The seminal vesicle is one of the most complicated sacs met with in human anatomy, and has been thoroughly studied by Picker.[6] He gives five types:—

	Per cent.
1. Simple straight tubes	3·5
2. Wide canal without diverticula	15
3. Slender sinuous canal with or without diverticula	15
4. Straight with large diverticula	33
5. Short canal with large irregular diverticula ..	33

It seems from this classification that only about 15 per cent. of cases of infection of the interior of the vesicle have a good chance of efficient drainage. The presence of diverticula is an impediment to complete cure and accounts for the chronicity of vesiculitis. They must also have a direct bearing on those cases of unaccountable relapse after months or years of freedom from symptoms. The relapse may occur after coitus with a partner in whom no trace of infection can be found and in whom no subsequent infection takes place, the presumption being that pus is liberated from a diverticulum and a fresh infection of the mucous membrane takes place. This theory is borne out to some extent by the observation of Weisz,[7] who reports a fresh attack of gonorrhœa after simple massage of the vesicle.

The tube bends on itself producing a number of shelves, and although fluid enters easily from the vas it is not so easy to empty the vesicles through the ejaculatory duct by digital pressure on the vesicle. In the dissected specimen it is impossible to empty it completely, even by firm pressure.

LIPIODOL INJECTIONS.

An attempt has been made to show the variations in the internal arrangement of the vesicles and ampulla of the vas by injection of dissected specimens with lipiodol, and although, owing to the difficulty of obtaining enough specimens, only 15 radiograms could be taken, the results are of some interest.

The base of the bladder was removed from the body with the vesicles attached. All redundant tissue was then removed until the vesicles showed as thin-walled sacs. The vas was then opened at the point where it curves round the side of the bladder and injected with lipiodol (lipiodol 1 part, liquid paraffin 2 parts). Dr. Ulysses Williams very kindly took the X ray photographs and has collaborated with me in the interpretation of the results.

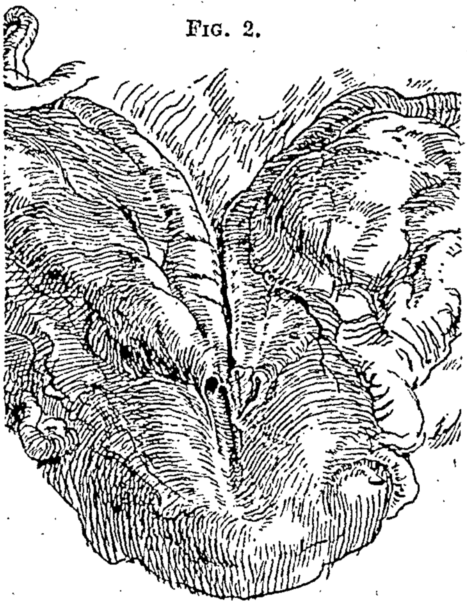
The vesicle shows as a coiled tube varying in complexity. In only one specimen (Fig. 3) is it a simple tube, on one side only, and even then it shows small diverticula. In Figs. 4 and 5 there seems to be partial blocking of the vesicle itself as the vas is injected. In Fig. 6 very little lipiodol has penetrated into the vesicle on one side, but this may be due to blocking of the vas.

The ampulla shows a good deal of variation. It extends further along the vas than is usually supposed, as shown in Fig. 7. In these cases the proximal end of the ampulla would be out of reach of the massaging finger. The amount of dilatation of the ampulla is another noticeable point as shown in Fig. 8. Diverticula were present in 12 out of the 15 specimens, as shown in Figs. 3, 4, 5, and 7. They were clubbed in seven, as shown in Figs. 5 and 7. The ampulla of the vas is another structure which lipiodol shows to be a complicated tube and one in which infection is liable to remain dormant as much as in the vesicle. Geraghty[8] stresses this in an article on vesiculotomy in which he maintains that when performing this operation it is important at the same time to incise the ampulla.

SPREAD OF INFECTION.

The method of spread of infection from the anterior urethra to the deeper parts of the urethra has been a subject of debate for years. Whether it be by lymphatics, continuity of mucous membrane, or blood stream is open to question. That it may arise as the outcome of too forcible injection during treatment appears not improbable. Konstam and Cave,[9] during their work on urethrograms, found in one case that a simple injection of the urethra with lipiodol gave a complete picture of the vesicles, and Bauer[10] had a similar experience. In neither case is there mention of the exact amount of pressure used for the injection. I do not wish to argue from these two rare accidents that the occurrence is common

FIG. 2.

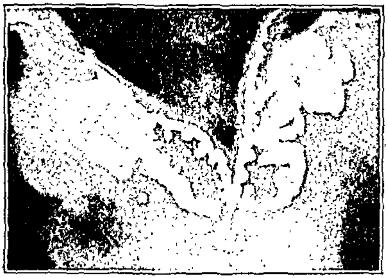


Drawing of dissected specimen showing relative size of openings into vesicle and ampulla at their junction.

or that, on this account, the use of a syringe under proper conditions is dangerous, but it does seem to show that spread of infection to the vesicle may be much easier than is thought.

If the spread is direct, the opinion of those who think that in epididymitis the vesicle is always infected as well is strengthened, because infection must pass across the opening of the vesicle, which, as is seen in Fig. 1, is comparatively large. Jordan Lloyd[11] pointed out that infection has a shorter distance to travel to the vesicles than to the epididymis and maintained that infection of the former is far commoner than is thought. This opinion was formed in 1889, and there has been very little English literature on the subject since then until quite recently.

FIG. 3.



Figs. 3–8 are described in the text.

Belfield reports a case in which he discovered urine in the vas, and accounts for it by the fact that the patient had taken exercise with a full bladder during an acute attack of gonorrhœa, the assumption being that the relaxed bladder sphincter allowed urine to leak into the posterior urethra and carry infection to the ejaculatory ducts.

Pathology.—Different degrees of inflammation of the mucous, muscular, and perivesicular tissues have been described, but mostly on clinical grounds. One of the conditions shown by injection of the vas with opaque fluids is the breaking-down of the partitions between the different lobes, and Barney[12] states that one undivided mass (as shown in his radiograms) indicates this breaking down. One would expect this to be the beginning of the formation of a true spermatocystitis in which the vesicle is reduced to a bag of pus.

Picker[6] divides his cases up clinically, according to his description of the internal anatomy, into those with good and bad drainage. Those with a simple tube drain easily, those with a twisted tube heal more slowly, and those with many diverticula become chronic.

Diagnosis.

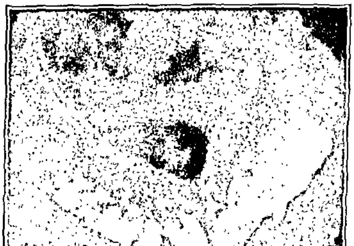
Acute Cases.—The incidence of posterior urethritis is put as high as 90 per cent.[13] by some authors, and therefore the chance of infection of the vesicles via the ejaculatory duct is likely to be as high as this. Chauvin[14] thinks that one-third of all cases of acute gonorrhœa have vesicle infection. Experience gained during the war confirms this incidence of posterior urethritis, as an attempt was made in every case to ascertain whether on arrival in hospital infection had spread to the posterior urethra; a urethritis confined to the anterior urethra was a rare discovery. The onset of a posterior urethritis may be silent, on account of the mildness of the inflammation produced, and during the course of treatment may heal completely.

The well-known symptoms accompanying a more acute infection, such as strangury, difficulty in micturition, cessation of discharge, and perhaps a little hæmaturia during the first week of an acute attack, or, at another typical period, three weeks after infection, should arouse suspicions that the infection may have spread to the vesicles. I do not mean that the symptoms mentioned are due to an infected vesicle, but that if the inflammation is so acute as to produce such symptoms there is more chance of the infection having spread. I do not think that vesicle infection is looked for or infection suspected often enough; serious constitutional disturbance at the beginning of an acute gonorrhœa is more frequently ascribed to a lack of resistance of the individual to a virulent organism than to infection of any particular part of the urinary tract.

An infected sac in other parts of the body with such poor drainage as the vesicle always gives rise to constitutional disturbance, and it is reasonable to assume that the same may be true of the vesicle. In most cases of acute gonorrhœa there is some rise of temperature in the evening, but if this should rise as high as 102° or 103°, especially with symptoms of synovitis, vesicle infection should be suspected.

A large number of these cases are never suspected, and if the anatomy of the vesicle is a simple one drainage is good and the case clears up quickly. If the condition is suspected the possibility of a subsequent chronic vesiculitis should be borne in mind and after convalescence these cases should be submitted to a searching examination. The great difficulty is the silence of the disease and the fact that there are no signs or symptoms which can be stated to be pathognomonic. On account of the loose covering of the vesicle a considerable amount of distension can take place without causing pain and, unless there is complete blocking of the duct, symptoms are not likely to draw attention to the infection.

FIG. 4.

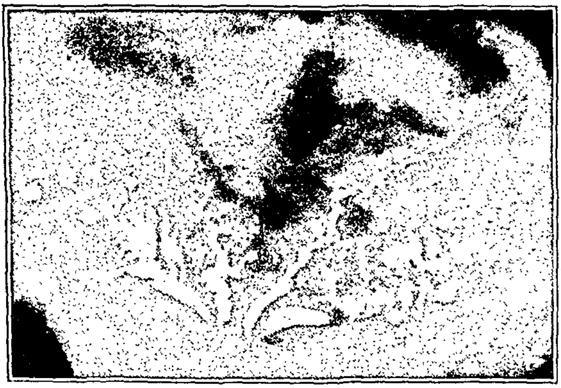


Mention must be made of those rare cases written of by Jordan Lloyd[4] in which there is an acute spermatocystitis with blocking of the ejaculatory duct and spread of infection into the cellular tissue. Here there is at once the appearance of serious illness, with high temperature, perineal and rectal pain, relieved by emptying the bladder, and frequency of micturition.

In the milder forms of vesiculitis, on which I wish to lay stress, two symptoms may be present: hæmospermia—which is rare—and priapism. Pain, if present, is more likely to be due to an associated prostatitis, on account of the toughness of the capsule of the prostate, which resists stretching. Of signs there are few and rectal examination is disappointing, as these vesicles cannot be felt in the acute state. There is, however, one sign which may have a bearing on the condition. If rectal examination is made with the patient in the knee-elbow position during the acute stage of a severe attack of gonorrhœa, a turgescence can sometimes be felt which spreads over and above the prostate, obliterating its characteristic outline and shape. Although no proof can be given for ascribing this turgescence to an inflammatory condition of the cellular tissue beneath the fascia of Denonvilliers, it seems not unlikely to be the case. The condition clears up quite quickly and the prostate regains its normal shape and outline.

Chronic Cases.—The history of an undoubted chronic vesiculitis generally shows that during the original acute attack there was at some time a more serious aspect of the case such as epididymitis, high temperature, or joint pains. Cases of recurring epididymitis, first on one side and then on the other, known to the French as "epididymite à bascule," do not appear to be common in this country, but are looked upon in France as pathognomonic of vesicle infection. This relapsing epididymitis may equally well be caused by prostatic infection. The symptoms which may be present are a most inveterate gleet, chronic haziness of the urine, and rheumatism in a man who has at some time had a troublesome gonorrhœa. Gleet may be present alone in the absence of any discoverable cause.

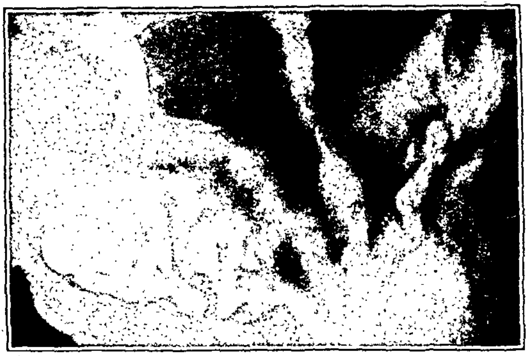
FIG. 5.



Microscopically the pus from the meatus may be mostly old and degenerated, but now and then fresh pus may appear which stains well. Organisms of a secondary infection may be present, and occasionally the gonococcus. On account of the intermittent appearance of the gonococcus, repeated examination for it should be made. In a case under my care eight months elapsed before a good specimen could be obtained. The macroscopic appearance of the gleet varies from a thin, sticky secretion to a genuine yellow pus, and, characteristically, it may be absent for weeks and then appear again. It usually yields quickly to urethrovesical lavage.

In a relapsing chronic case of gonorrhœa the haziness of the urine, as described by Kidd,[15] is very suggestive. This haziness is present when other causes of a hazy urine have been excluded and if the anterior urethra has been thoroughly washed before urine is passed. On the other hand, the urine may be clear, and this may be explained by the fact that the emptying of the vesicles is intermittent and the examination may be made soon after the vesicle has emptied itself. In the presence of a gleet and a hazy urine rheumatism is commonly present and attacks muscles as well as joints. Hæmospermia is an uncommon symptom in either acute or chronic vesiculitis. It is looked upon by some as pathognomonic.

FIG. 6.



Symptoms may be almost absent and the condition may come to light only in the investigation of an obscure case of rheumatism and the discovery of a hazy urine.

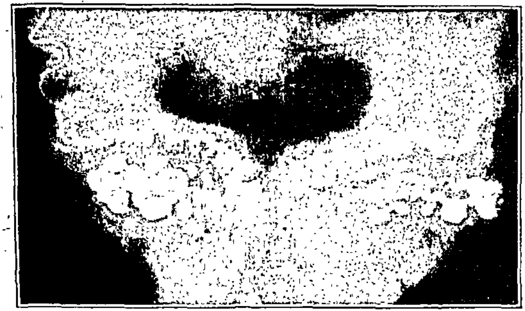
The anterior urethra should be thoroughly explored for infected Littré's glands and the posterior urethra for abscesses and pockets which drain badly. It is possible, though it is rare, to see pus exuding from the ejaculatory duct. I have seen this once only. The posterior urethroscopy should be made at least a fortnight before the vesicles are investigated, because this examination, although causing very little disturbance to the patient, may give the urine a hazy appearance which clears up in a few days. The anterior urethra is washed by irrigation with sterile saline until the washings return clear. The urine is then passed into a glass; it may have the typical haze due to pus. The bladder is filled with saline by Janet's method and immediately evacuated by the patient. This ensures that both the anterior and posterior urethra are free of pus or débris. The bladder is filled for the second time with saline. If it is difficult for the patient to relax his compressor sufficiently to allow saline to enter his bladder an injection of 5 per cent. novocain into the anterior urethra can be held in with a penile clamp.

RECTAL EXAMINATION.

The next procedure is rectal examination, which plays an important part both in diagnosis and treatment. Much has been written about examination and massage of the prostate and vesicles, and opinions vary from those who maintain that there is little to be gained by the method to those—like François quoted by Chauvain[14]—who maintains that he is able to differentiate five separate forms of vesiculitis!

I decided to investigate 35 cases in the post-mortem room to see whether the vesicles could be satisfactorily reached by the examining finger. The cadaver was placed in a leaning position over the side of the table. The sacrum was removed, leaving the coccyx with its lateral attachments. The vesicles were then sufficiently exposed to view without removing the rectum. It was found that with a finger of average length inserted into the rectum every part of the vesicle could be reached in the majority of cases, but that the vesicles, if normal, could not be felt as distinct structures. In some cases, however, where the prostate was enlarged in the anteroposterior direction, the finger by no means reached the vesicle satisfactorily. Sometimes the vesicle is more vertically placed on the posterior surface of the bladder than the usually accepted horizontal position, and this may place its fundus out of reach.

FIG. 7.



Therefore, in massage of the vesicles, the observer must be absolutely sure of being able to reach the upper margin of the prostate. If this can be done, most efficient massage can be carried out. In the great majority of cases of vesiculitis the vesicle cannot be felt and massage should be done along the upper margin of the prostate, as this corresponds exactly with the position of the vesicle. For palpation of the ampulla of the vas the beginning of the V-shaped portion of the prostate should be sought, as this corresponds with the position of the ampulla. Sometimes a thickening can be felt in this position.

Another fact which interferes with the efficient massage of the vesicle is a deep perineum in a fat subject, when the finger may fail to reach beyond the middle of the prostate.

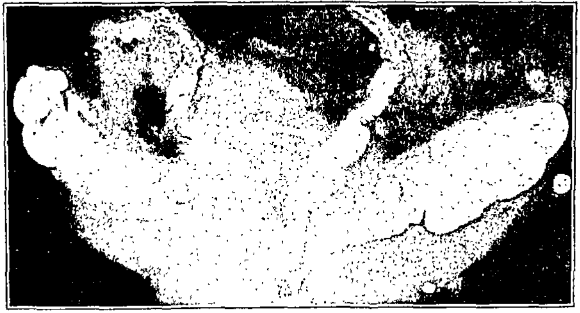
In rectal examination of the living subject in the knee-elbow position, a hand on the abdomen pushing down the pelvic contents is a great help. A proof that the vesicles are often impalpable is the fact that indiscriminate massage of the prostate will often bring away the flocculent masses typical of vesicle secretion without the surgeon being aware that he has touched more than the prostate. After the bladder has been filled for the second time the prostate and vesicles are massaged together.

Chauvain[14] recommends massaging prostate and vesicle separately and quotes Cabot as doing the same thing, and for this purpose filling the bladder a third time, but anyone who has had experience of rectal examination in these cases knows that such separation is hardly practicable. Some help in diagnosis is forthcoming from the feel of the prostate, which is so readily palpable; tenderness, hardness, or even fluctuation may point to a prostatitis. It is, however, important for the bladder to be filled with saline, as subsequent passage of its contents by the patient will wash secretion away which may have fallen back into the bladder. Preparation is made for the collection in a watch-glass of any secretion which may come from the meatus during the massage, and films are made from this in search for pus or organisms. If cultural examination is desired the meatus must be carefully cleaned with spirit, and the urine must be passed into a sterile bottle through a sterilised glass funnel. It is important to use sterile saline in preference to weak antiseptic, because the latter interferes with the staining properties of pus and organisms.

EXAMINATION OF SECRETION.

The macroscopic appearance of saline passed after massage of the prostate and vesicle is important and helpful. The fluid may be clear with solid particles or cloudy with solid particles. The cloudiness may be due to phosphates or free pus. The addition of a little acetic acid will at once eliminate phosphates, but some of the fluid should be set aside for microscopic examination before the acid is added. Both of these appearances may be due to an infected prostate. If the precaution has been taken of examining the posterior urethra, as previously suggested, and any gross lesion of that part eliminated, no quantity of pus is likely to come from the prostate.

FIG. 8.

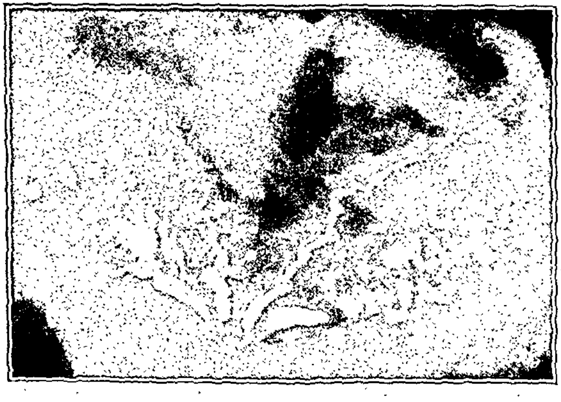


The most characteristic appearance of vesicle secretion in saline is the presence of large flocculent spermatocystitis with blocking of the ejaculatory duct and spread of infection into the cellular tissue. Here there is at once the appearance of serious illness, with high temperature, perineal and rectal pain, relieved by emptying the bladder, and frequency of micturition.

In the milder forms of vesiculitis, on which I wish to lay stress, two symptoms may be present: hæmospermia—which is rare—and priapism. Pain, if present, is more likely to be due to an associated prostatitis, on account of the toughness of the capsule of the prostate, which resists stretching. Of signs there are few and rectal examination is disappointing, as these vesicles cannot be felt in the acute state. There is, however, one sign which may have a bearing on the condition. If rectal examination is made with the patient in the knee-elbow position during the acute stage of a severe attack of gonorrhœa, a turgescence can sometimes be felt which spreads over and above the prostate, obliterating its characteristic outline and shape. Although no proof can be given for ascribing this turgescence to an inflammatory condition of the cellular tissue beneath the fascia of Denonvilliers, it seems not unlikely to be the case. The condition clears up quite quickly and the prostate regains its normal shape and outline.

Chronic Cases.—The history of an undoubted chronic vesiculitis generally shows that during the original acute attack there was at some time a more serious aspect of the case such as epididymitis, high temperature, or joint pains. Cases of recurring epididymitis, first on one side and then on the other, known to the French as "epididymite à bascule," do not appear to be common in this country, but are looked upon in France as pathognomonic of vesicle infection. This relapsing epididymitis may equally well be caused by prostatic infection. The symptoms which may be present are a most inveterate gleet, chronic haziness of the urine, and rheumatism in a man who has at some time had a troublesome gonorrhœa. Gleet may be present alone in the absence of any discoverable cause.

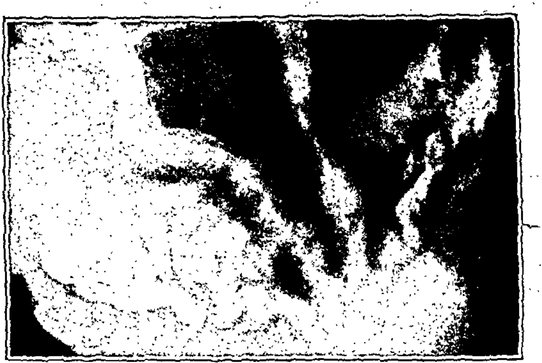
FIG. 5.



Microscopically the pus from the meatus may be mostly old and degenerated, but now and then fresh pus may appear which stains well. Organisms of a secondary infection may be present, and occasionally the gonococcus. On account of the intermittent appearance of the gonococcus, repeated examination for it should be made. In a case under my care eight months elapsed before a good specimen could be obtained. The macroscopic appearance of the gleet varies from a thin, sticky secretion to a genuine yellow pus, and, characteristically, it may be absent for weeks and then appear again. It usually yields quickly to urethrovesical lavage.

In a relapsing chronic case of gonorrhœa the haziness of the urine, as described by Kidd,[15] is very suggestive. This haziness is present when other causes of a hazy urine have been excluded and if the anterior urethra has been thoroughly washed before urine is passed. On the other hand, the urine may be clear, and this may be explained by the fact that the emptying of the vesicles is intermittent and the examination may be made soon after the vesicle has emptied itself. In the presence of a gleet and a hazy urine rheumatism is commonly present and attacks muscles as well as joints. Hæmospermia is an uncommon symptom in either acute or chronic vesiculitis. It is looked upon by some as pathognomonic.

FIG. 6.



Symptoms may be almost absent and the condition may come to light only in the investigation of an obscure case of rheumatism and the discovery of a hazy urine.

The anterior urethra should be thoroughly explored for infected Littré's glands and the posterior urethra for abscesses and pockets which drain badly. It is possible, though it is rare, to see pus exuding from the ejaculatory duct. I have seen this once only. The posterior urethroscopy should be made at least a fortnight before the vesicles are investigated, because this examination, although causing very little disturbance to the patient, may give the urine a hazy appearance which clears up in a few days. The anterior urethra is washed by irrigation with sterile saline until the washings return clear. The urine is then passed into a glass; it may have the typical haze due to pus. The bladder is filled with saline by Janet's method and immediately evacuated by the patient. This ensures that both the anterior and posterior urethra are free of pus or débris. The bladder is filled for the second time with saline. If it is difficult for the patient to relax his compressor sufficiently to allow saline to enter his bladder an injection of 5 per cent. novocain into the anterior urethra can be held in with a penile clamp.

RECTAL EXAMINATION.

The next procedure is rectal examination, which plays an important part both in diagnosis and treatment. Much has been written about examination and massage of the prostate and vesicles, and opinions vary from those who maintain that there is little to be gained by the method to those—like François quoted by Chauvain[14]—who maintains procedure, on account of the amount of pressure necessary to occlude such a thick-walled tube.

The antiseptics for injection are numerous, but those mostly used are collargol 5 to 10 per cent., argyrol 5, 10, and 25 per cent., silver nitrate 1 to 2 per cent., and silver protein (Thomas) 20 per cent.

VASOTOMY.

Although no large number of cases of successful vasotomy has been published in British literature there is ample evidence of the success of this small operation in other countries. Belfield, in 1143 cases, had 80 per cent. of cures, Cumming[18] reports 336 cases, and Thomas 94[3] with 37 per cent. of cures. Cumming and Glenn[17] record 65 cases with 61 per cent. of cures, and Baker[21] 75 cases with 40 per cent. of cures.

An important objection to the operation is the slight risk of stricture of the vas and consequent sterility on that side. Thomas and Birdsall,[22] experimenting on 20 dogs, found that stricture occurred in half the cases of vasotomy and in only 5 per cent. of vasopuncture. They used 5 and 10 per cent. collargol. In the vasotomy cases the vas was sewn up with catgut. When stricture occurred it was always at the site of incision of the vas. This would appear to be an argument in favour of vasopuncture, although the vas of the dog may not be comparable with that of man.

Whatever the exact function of the seminal vesicle, one rôle ascribed to it is an influence on the fecundity of spermatozoa. Whether this be so or not a chronically inflamed vesicle is not one which can carry on its function normally, and it is possible that restoration of the vesicle to normal may account for cases reported by Luys and Cumming[18] in which spermatozoa, absent before vasotomy and lavage of the vesicles, have reappeared afterwards. In an analysis of 87 cases of suspected vesicle infection in which histological examination of the semen was made, Luys[1] found that 23 per cent. contained no spermatozoa, which means that in vesicle infection about 25 per cent. of cases are sterile. Belfield[23] had sufficient confidence in the operation to operate on four men each with only one testicle. After vasotomy the semen was normal in all four cases. Clinton Smith,[24] who always does double vasotomy, reports 100 cases operated on; in 99 normal spermatozoa were present after operation.

In rebellious cases the only alternative to many months' treatment is vasotomy, and although one injection may not cure at once it is a great help to further treatment along ordinary lines. It is maintained by some that after vasotomy drainage is better, and this is emphasised by Baker,[21] who reports that in four cases after vasopuncture the gonococcus, which was absent before operation, reappeared afterwards. As illustrated by the radiograms, infection of the ampulla of the vas must be looked upon as a potent cause of chronicity. Except by very indirect means, it is impossible to reach the infection in this position, as the whole ampulla cannot be reached by the massaging finger. The slow emptying of the vas—except by muscular contraction—combined with a simple type of mucous membrane may account for the good results of vasotomy. The antiseptic may remain in contact with the interior of the vesicle as long as 21 days. The evidence of this is that urine may be stained with collargol or argyrol for this period after injection of the vas.

There are writers who state that vesiculitis is always bilateral; and they advocate that vasotomy should always be done on both sides. Recurrent epididymitis on one side only would point to infection of the ampulla and vesicle of that side and would indicate a single vasotomy.

If sterility due to double epididymitis already exists, the production of another stricture higher up the vas does not add to the patient's disability. If, on the other hand, the sterility be due to an inflammatory condition of the vesicle, fertility might be re-established. An argument in favour of earlier operation is that the small diverticula are less likely to be shut off by chronic inflammation which would prevent antiseptics reaching them. I do not wish to advocate that this little operation should be undertaken light-heartedly, but all authors agree that good technique minimises the incidence of stricture.

Case Report.

A man, aged 25 years, contracted gonorrhœa for the first time in India in May, 1928. He irrigated himself with potassium permanganate for 15 days, when the discharge suddenly stopped. Three days later left epididymitis developed, and intravenous iodine was given. Four days later right epididymitis appeared. He then went to hospital and remained there two months. The right side subsided, but the left, after recovering, relapsed. After a month in hospital some massage of the prostate was done and the only other treatment was intravenous sodium iodide. After leaving hospital he gave himself vaccines and reported to me that whenever he took alcohol the meatal discharge returned.

He was first seen by me on Feb. 18th, 1929. There was then a little mucoid secretion at the meatus which contained only degenerate pus cells, but no gonococci. The anterior urethra was irrigated and the washings contained a few pus threads, but one wash was sufficient to clean it. The urine was then passed and was hazy and contained pus threads. The bladder was filled with saline by Janet's method. The prostate was normal in size and consistency. The vesicles could easily be reached but could not be distinguished as palpable organs. In the position of the ampulla of the vas a pea-like body could be felt on each side of the middle line; these were diagnosed as thickenings in the ampulla.

The saline passed after massage contained free pus but no gonococci. On Feb. 20th thin pus appeared at the meatus and typical gonococci were found. On Feb. 27th under general anæsthesia the posterior urethra was examined. The verumontanum appeared healthy, no old prostatic abscess was seen, and the ejaculatory ducts were not visible. From March 4th until May 21st the prostate and vesicles were massaged about every four days and, although the urine began to clear and the amount of secretion expressed as seen in saline passed after massage was far less, the gonococcus was still present in films from the meatus. In addition to massage diathermy per rectum had been given and also instillations into the posterior urethra of 5 and 10 per cent. argyrol. The patient now began to complain of rheumatism in joints and back, and in spite of continuous treatment the gonococcus could still be found in films. The anterior urethra was carefully explored for any possible focus of infection, with negative result. A fresh specimen of semen was examined and found to contain almost pure pus. No spermatozoa or gonococci were found.

I decided to do a double vasotomy and wash out the vesicles for the following reasons: (1) the gonococcus was still present; (2) there was good reason to think that the vesicle was the part of the urinary tract infected; (3) the patient had coöperated fully in treatment for five months; (4) rheumatism had begun and was getting worse; (5) the patient was sterile, following double epididymitis; and (6) he was very anxious to get well and resume his occupation in the tropics.

On July 25th, 1929, under general anæsthesia, the right vas was exposed by a small incision at the lower end of the inguinal canal, incised, and injected with 9 c.cm. of 10 per cent. argyrol. The same was done on the left side, but as there was more resistance to the flow of the argyrol on this side only 5 c.cm. were injected. On both sides about 1 c.cm. of sterile saline was injected before the argyrol in order to ascertain that the lumen of the vas was clear. The vas was closed with 5/0 catgut. The urine was stained with argyrol for a few days. All signs and symptoms cleared up without further treatment.

Six months later saline passed after massage of the vesicles was reported as containing no pus or bacteria.

Fresh semen was free of pus, but there were still no spermatozoa. The urine was clear.

Summary.

1. Catheterisation of the ejaculatory ducts and lavage of the vesicle by this means is not practicable at present.

2. During the treatment of acute gonorrhœa the possibility of infection of the vesicles should be borne in mind, especially in those cases which show severe illness or early complications. These should be carefully scrutinised after convalescence.

3. The investigation should follow the lines suggested under diagnosis.

4. Indications for vasotomy:—

(*a*) In protracted cases lasting over five months in whom other treatment has been tried, especially if rheumatism is present.

(*b*) In resistant cases in whom, owing to a deep perineum, it is impossible to massage the vesicles efficiently.

(*c*) In cases where the coöperation of the patient is doubtful during a long course of treatment and where the disease hinders him from continuing his occupation.

(*d*) Where sterility is already established by previous double epididymitis.

BIRMINGHAM HOSPITALS.—The report for 1930 of the Birmingham General Hospital states that the financial position is now very serious. There is an overdraft of £20,000 in excess of the remaining unsold free investments, and the governors recently decided to promote a Bill in Parliament for the amalgamation of the General and the Queen's Hospitals. A committee of three experts has been appointed to investigate the position, and representatives of the hospitals council are to discuss how best the financial difficulty can be removed without detriment to the work. In 1930 the income was £79,902 and the expenditure £100,779; in the preceding year the income was £82,656 and the expenditure £90,611. The report states that the Queen's Hospital is in a similar position. It had been expected that the contributory scheme would be able to pay £3 a week in respect of members admitted, and the governors' financial policy had been based on that assumption, but at present the scheme can pay only about half that amount. In-patients last year numbered 7682, an increase of 625; out-patients were 59,282, an increase of more than 1400.

THE IMPORTANCE OF KERATOMALACIA AS A CAUSE OF BLINDNESS IN INDIA.

By R. E. WRIGHT, C.I.E., M.D. DUB.,

LIEUT.-COLONEL, I.M.S.; PROFESSOR OF OPHTHALMOLOGY, MEDICAL COLLEGE, AND SUPERINTENDENT, GOVERNMENT OPHTHALMIC HOSPITAL, MADRAS, INDIA.

WITHIN the past year keratomalacia has figured somewhat prominently in current medical literature. Various features of the condition (so-called), which is very familiar to ophthalmologists in many parts of the Orient, have been presented afresh to the profession in a more interesting light, and previously unrecorded clinical evidences of this deficiency-complex have been noted. Prominent amongst the papers which have appeared are those by Pillat of Vienna,[1] based on material studied in China. He has presented a study of keratomalacia as met with in the adult which, despite errors and omissions, is perhaps the most complete and up-to-date assemblage of the diverse pathological changes which go to make up this complicated clinical picture of deficiency disease; for all practical purposes his exposition serves equally well for children. To my mind, however, the one great outstanding feature of keratomalacia is its enormous importance as a cause of preventable blindness. This aspect of the disease has not yet been fully appreciated, even by observers of the condition who live in countries like India, where, according to McCarrison,[2] faulty nutrition is the great basic cause of the bulk of the ill-health. Pillat does refer to it, but with scarcely sufficient emphasis; he says: "Keratomalacia of adults as well as in children ends so frequently in blindness in China that it represents also a social problem to which the attention of the government and officials should be turned."[3]

I have for several years felt much more strongly than this on the economic question, and my experiences and observations extending over a decade lead me to state that keratomalacia is almost certainly the chief cause of preventable blindness in children in the greater portion of the Indian Empire, and where similar conditions of malnutrition exist in other parts of the world it is likely to be of similar importance. I say "almost certainly," because it is impossible to prove such statements by recourse to records in a manner which would satisfy a statistician. Figures for the general public are unobtainable, so we must form opinions from our hospital population. In so far as the Madras Hospital is concerned—and it deals with about 20,000 out-patients per annum, fairly representative of the South Indian population—keratomalacia is responsible for more blindness amongst children than any of the other great blinding conditions of youth—i.e., irritant remedies, smallpox, ophthalmia neonatorum, syphilis, and trachoma. Last year, for example, 187 cases of keratomalacia were registered at the out-patient department. Dr. P. A. Narayana Iyer, in charge of this department, kept a special record of 95 of the more advanced of these in which the eye lesion threatened vision. The record shows that 67 were under 5 years of age, that total blindness occurred in 30 cases, and practical blindness in 70 per cent. As compared with this, there were 59 cases of ophthalmia neonatorum and lesser numbers of the other conditions mentioned above. In only five of the 59 was vision totally lost, and in only three others was it seriously interfered with. Our experience has been that blindness is a very much more common sequel to keratomalacia than to ophthalmia neonatorum. This may possibly be associated with the fact that gonorrhœa, especially ophthalmia neonatorum, appears to run a milder course in this part of India than it does in England.

Coming first in the blinding diseases of youth, the importance of keratomalacia as a blinding disease at all ages may be gathered from a comparison with the position in England and Wales, where ophthalmia neonatorum is held to be the chief cause of blindness.[4] Although the actual number of blind under 5 years of age in England and Wales for recently recorded years is small (under 500 in 1911 and under 300 in 1927), and not half of this number is accounted for by ophthalmia neonatorum, still its effect calculated up through the different age-groups, in spite of the lessening effect of the death-rate, makes ophthalmia neonatorum the greatest single cause of blindness. Causes such as ophthalmia neonatorum which operate heavily during the first five years apparently have a major influence on the total number of blind persons.

Assuming that no other massive causes of preventable blindness come into play during the later age-groups in the Madras Presidency, it is perhaps permissible to argue that, if keratomalacia is our greatest cause of blindness in the first five years of life, it is also the greatest probable cause of preventable blindness at all ages. Looking at the actual census figures for the Madras Presidency, 1921, we find that the total number of blind (37,162) is less than that for England and Wales for 1911; but the number of blind at five and under in Madras (768) is enormously greater, which appears to strengthen the argument. The Indian census report gives as its final age-group, "70 and over," and at this period we find an enormous rise in the actual number of blind as compared with the numbers in the preceding five-yearly periods. Such a rise, however, in a combined group of the last few age-periods hardly affects the question, even though it may be accounted for by a single cause; cataract, for example, with which we are not concerned as the definition "preventable" excludes it.

Keratomalacia, then, in so far as we are able to estimate, is the greatest cause of preventable blindness in the Madras Presidency in the first five years of life, a much greater cause in these years here than is ophthalmia neonatorum in England and Wales. This position with regard to keratomalacia is not, however, peculiar to the Madras Presidency. The professors of ophthalmology at Calcutta, Bombay, and Lucknow, Lieut.-Colonels Kirwan and Duggan, and Dr. Acharya, assure me that the same is true in Bengal, Bombay, and the United Provinces respectively. On the other hand, Colonel Dick, professor of ophthalmology, Lahore, informs me that keratomalacia is practically unknown in the Punjab. One of the great differences between the Punjab and the other areas mentioned above which influences the occurrence of keratomalacia is that the food in the Punjab gives a more complete diet, as pointed out by McCarrison.[5] The inhabitants are largely wheat-eaters, not rice-eaters; moreover, the Punjabis also consume larger quantities of milk and milk products and other vitamin A-bearing foods. Hence there is very little deficiency disease in the Punjab.

The disease in adults, if not so frequently met with in India, has been well recognised, although one might gather from Pillat's work that it was practically unknown. Undoubtedly in India the disease as observed in children had been much more stressed because of its greater frequency, but the disease in adults was well known and recognised in the teaching ophthalmic centres throughout this country. For example, in Maynard's "Manual of Ophthalmic Practice," largely used by students in this country for a number of years, we find, "the condition is not infrequently seen in adults." Nor is Pillat correct in thinking that I omitted to give relative figures for adult keratomalacia, or that my recognition of keratomalacia in the adult was based on Kirkpatrick's opinion. The disease in adults and also its relative frequency and importance as compared with the juvenile disease were well known to me, and actual figures are given in my annual hospital reports for 1921 and 1922.[6] Now, although adult keratomalacia is not so common in India as it appears to be in China, yet the fact of its occurrence in appreciable amount adds still further to its influence on the total blindness in the country, because, unlike ophthalmia neonatorum, it operates through all the age-periods.

Importance of Various Vitamins.

It is, I think, unfortunate that the name keratomalacia should be used for a generalised disorder of malnutrition in which ophthalmic features, however noteworthy, are but localised signs of a multiple deficiency-complex. The chief primary ætiological factor—but not the only factor, in so far as our present knowledge goes—would appear to be a lack of fat-soluble vitamin A in the diet. It had long been recognised that the various eye signs and symptoms and the many other associated pathological states of the body in this disorder were primarily due to malnutrition. Later, the whole gamut of changes was ascribed, perhaps prematurely, to a deficiency in vitamin A. To-day, however, there are some who consider that it is not a pure vitamin-A deficiency but a multiple deficiency. Some years ago, in looking for other elements in this complex, I held and promulgated many mistaken ideas on the subject of keratomalacia, and probably continue to do so. Some of my former ideas were published, in connexion with the clinical investigations which have been undertaken in our out-patient department for the past ten years, in the annual reports of the hospital. To-day, however, I would hardly be bold enough to say that the clinical condition so well known here in all its phases, both in children and adults, as keratomalacia, was even initially due to a deficiency in vitamin A alone. In discussing this question with Colonel McCarrison recently, I gathered that there is much to suggest that vitamin-B deficiency may play a part in causing its protean manifestations. I refer, of course, to the earliest evidences of the deficiency complex; later on, the organs and tissues damaged by the primary deficiency cease to play their normal rôle, and there are secondary disturbances due to altered function—e.g., endocrine function. It is very difficult, even under conditions of experimental research in animals, rigidly to exclude all but one known vitamin from the diet. In clinical investigations it is impossible to observe the effect of a steady insufficiency of any one essential food factor, and so experimental work with human material is exceedingly hard to plan and interpret. The experimentally produced animal disease probably presents much truer and simpler pictures than those seen in the clinic. Some years ago I did not take this sufficiently into account, and failed to give proper credit to the fact that the human condition known as keratomalacia was a deficiency-complex involving a greater number of factors than the experimental one known as xerophthalmia, and that this was sufficient to account for the apparent differences met with under natural and experimental conditions.

In so far as human cases are concerned, after various essays in experimental feeding we are at least able to say that crude cod-liver oil in suitable doses is the most effective agent in eliminating the major signs and symptoms of this deficiency-complex. This oil is probably largely effective by virtue of its vitamin-A content, but it also contains vitamins B, C, and D. There is no proof that it is the fat-soluble vitamin A alone in cod-liver oil which produces the beneficial effects in keratomalacia. Recently Dr. R. Muthayya of my staff has administered pure fat-soluble A (B.D.H.), kindly supplied by Colonel McCarrison to children suffering from this disease, but they did not improve so rapidly as they ought to have done on crude cod-liver oil. In all probability it requires an initial multiple vitamin deficiency, with a secondary multiple dysfunction of glandular structures to account for the whole picture of degeneration, loss of function, wasting, necrosis, secondary infection, and death, which we see in keratomalacia. It seems more than likely that the principal initial factor is an A-deficiency and that certain of the prominent clinical features are due to the effects of this deficiency on important tissues and organs of the body, such as the epithelial surfaces of the integument and mucous membranes and their glandular diverticulæ.

Secondary Infection.

Animal experimentalists appear to lay a great deal of stress on bacterial invasion as a primary resultant of vitamin-A deficiency. This vitamin may be more important to animals in an anti-infective rôle than it is to man, because clinically it is difficult to find much support for this hypothesis. In man masses of organisms can be found in the epithelial debris of which some of the discharges are largely made up, but a localised necrosis may occur—e.g., in the cornea—without any of the evidences of acute organismal infection. An extensive necrosis of the substantia propria may be present with a practically intact epithelium. As Pillat shows,[7] a patient may have a most indolent undermined skin ulcer, with a minimum of inflammatory response, in which the ordinary pathogenic organisms carry on a localised and apparently saphrophytic existence. Organismal infection, as the clinician understands it, is only seen as a terminal event. Children may drag on for weeks in a state of extreme marasmus, with recognisable pathogenic organisms present in large numbers in their usual areas of invasion—e.g., respiratory tract, skin, and conjunctiva—without any specific change taking place. Such children may be transformed in a fortnight by cod-liver oil—sometimes administered on a flannel binder when the alimentary tract is too damaged to retain or use it—in a way that they could never be if bacterial invasion were the key to the position.

The primary pathological picture in the keratomalacia deficiency-complex is one of degeneration and wasting of epithelial surfaces, almost as distinctive a process as any of the classical degenerations. There is a tendency to proliferation, and metamorphosis to a lower type; columnar cubical epithelium tends to become squamous—e.g., in the respiratory tract. In certain situations—e.g., the skin—the pathological change is akin to the degenerative changes of senility. The clinical impression conveyed is that the effect of organismal attack in human keratomalacia is a late secondary association. Rises of temperature and blood changes are also probably secondary. I have seen numbers of keratomalacia cases, even moderately advanced, continue for weeks without a rise in temperature, but it is easy to picture how fever might be secondarily produced.

Some years ago thyroid extract was administered here as part of our routine treatment in keratomalacia, without knowing whether it would do good in the absence of cod-liver oil. We have discontinued it, as cod-liver oil by itself serves the purpose equally well. McCarrison[8] has recently demonstrated the histopathological changes in the thyroid and upper respiratory passages of white rats fed on a diet insufficient in fat-soluble vitamin. Presumably there are similar changes in the human subject, and no doubt the damaged thyroid plays a secondary rôle, but we do not know to what extent these changes are resolved by the administration of a sufficiency of vitamin A in the diet once they have started. The epithelial changes which he has described in the tracheal lining are probably very similar to those which occur in the respiratory passages in human keratomalacia.

Associated Clinical Features.

There are certain clinical features of keratomalacia which may perhaps be viewed in the light of chance associations. Prominent amongst these in South India is the association of keratomalacia and liver disease, both in adults and children. It seems to be more common in the adult, but then we see fewer cases of adult keratomalacia, and liver disease is more common in the adult general population. Some years ago I considered that this combination was much more than an association, and laid unnecessary stress on the rôle of the liver in this disease. It would be foolish to deny that the liver may become deranged late in fat-soluble deficiency, and, like the simple secreting glands of the integument and alimentary canal or the thyroid, undergo definite changes in structure and function with the production of secondary changes which in time become summated to the disease complex, but I now know that the liver may be apparently perfectly normal in advanced keratomalacia, in so far as can be made out by clinical methods and modern biochemical tests. The opportunity of seeing a diseased liver in a keratomalacic subject post mortem is rare in this hospital, and was not forthcoming until this year (January, 1930), when an adult with well-marked keratomalacia, who was jaundiced and whose liver appeared to be about normal in size, suddenly died. Even in this case I was only able to obtain a hurried examination through a "surgical" incision, as the friends were expected. The greenish, slightly roughened organ presented all the appearances of biliary cirrhosis so commonly met with here, and the microscopic examination showed the change to be of the typical obstructive type. I have no doubt that, in such Madrasi children as show an association of liver disease and keratomalacia, the usual post-mortem finding would be infantile biliary cirrhosis, a relatively common affection in children here.

I have pointed out elsewhere,[9] that a primary liver defect may be the deciding factor in precipitating generalised vitamin-A deficiency symptoms. The comparatively rapid onset of keratomalacia, in a patient living on a diet which had been efficient in keeping him apparently healthy until the development of primary carcinoma of the liver, is an example. It is well known that the liver stores fat-soluble vitamins, and perhaps it may even elaborate them. It is useless to speculate, as we now feel more confident that liver disease in keratomalacia is ordinarily a chance association—not the result of the deficiency—and the reason we see such a relatively large number of cases with this association is because liver disease in the general population is common in Madras.

Pillat does not lay much stress on jaundice and affections of the liver in keratomalacia in China; perhaps cirrhosis is not so common there. He does, however, produce definite evidence that the liver function, as tested by detailed biochemical methods, may be normal in adult keratomalacia. Some years ago we tried liver feeding as a method of treatment, but found it inferior to cod-liver oil.

The Conjunctivæ.

Icterus of the ocular membranes is not uncommon in keratomalacia in South India. Frequently the peculiar olivaceous effect of the characteristic smoky conjunctival pigmentation is superimposed on the yellow subconjunctival tissues, and similarly in the skin. Apart from jaundice, however, the keratomalacic patient sometimes presents a subicteric tinge both of skin and mucous membranes, but as a rule the smoky discoloration predominates. These three factors need not, however, be confused. The smoky pigmentation of the conjunctiva is one of the most characteristic signs of the keratomalacic complex and may be observed in its purest form as an early feature in apparently well-nurtured children, where the pigment is seen superimposed on normal subconjunctival tissues. Pillat and King,[10] in a discourse on the origin of this pigment, credited Kirkpatrick and myself with believing that the pigmentation was due to liver disturbance. Kirkpatrick,[11] reviewing their paper, repudiates this misrepresentation of his views, and I also must plead not guilty. Pictures illustrative of the eye signs in keratomalacia, made under Kirkpatrick's direction a number of years ago in Madras (copies of which may be seen in the London School of Hygiene and Tropical Medicine) make clearer than mere description the impression given to an observer of this smokiness. Pillat's suggestion that this pigmentation is indicative of suprarenal disease, although attractive, is opposed by the fact that the smokiness is one of the earliest signs of the malnutrition complex; in my experience it is often the second clear indication, night-blindness being the first. It is quite possible that the adrenal gland is affected in the keratomalacic deficiency-complex, since a pure uncomplicated deficiency of vitamin A in the food is never seen; there are necessarily other deficiencies associated with the A-deficiency. Of these the most common, in Madras at least, is deficiency of the B-vitamins (B and B_2). According to McCarrison,[12] of all the organs of the body the adrenals are the most susceptible to insufficiency of vitamin B. It is accordingly reasonable to expect signs of adrenal derangement. Probable reasoning, however, from the experimental evidence at our disposal, suggests that the gland becomes involved late, when other well-known results of the deprivation are already in evidence. Colonel McCarrison suggested that the smoky pigmentation of the eye and the otherwise inexplicable puffiness and œdema sometimes seen may be an expression of an adrenal dysfunction due to the effects of an associated vitamin-B deficiency; we have therefore undertaken an experiment with yeast feeding, but so far its results have been negative.

The second factor in abnormal pigmentation is the icteric or subicteric tinge. This is sometimes so marked as to give an impression of jaundice, but suitable biochemical tests readily prove that it is not true icterus. It is essentially a yellowness of the epithelial and subepithelial tissues. It is somewhat similar, perhaps, to the yellowness said to be due to hypercarotinæmia, but makes its appearance under opposite conditions. The third pigmentation, true icterus, has already been referred to and its frequency in Madras explained.

In spite of any opinions previously expressed to the contrary, I have no knowledge of any ophthalmoscopic intra-ocular changes which might be given a place in this complex, excepting such changes as may directly or indirectly result from the corneal lesion. Only on one occasion have I been able to examine the lenses of a baby born to a keratomalacic mother, and these were clear. This is of interest in view of von Szily's findings of lenticular changes in the sucklings of xerophthalmic white rat mothers.

In the present state of our knowledge the many interesting problems connected with this deficiency-complex are really more of academic interest than of practical importance to the ophthalmologist and public health worker. The discovery of the particular deficiency which is responsible for certain signs and symptoms is a problem which may well be left to the research worker who specialises in malnutritional disorders. That this particular malnutritional disorder should be the chief cause of preventable blindness in the Indian Empire is a matter of the greatest economic importance, but until the population becomes more nearly adjusted to its food-supply, it is difficult to see how things can be otherwise. Meanwhile, the prevention of the disease is more the concern of those departments of Government which have to do with the improvement of conditions of living and with the food-supply of the community than of the Medical Department. The general practitioner or ophthalmologist cannot do more than control those cases which come within his sphere of activities by the simple method of administering cod-liver oil. The issue of cod-liver oil on a large scale as a prophylactic measure in India would hardly be taken seriously by those who are responsible for the framing of our budgets.

The scanty references given will afford those interested in the subject a guide to the important clinical and experimental work done in this field before 1930.

ST. MARK'S HOSPITAL.—At the annual general meeting of the governors of this hospital in City-road, London, on March 19th, it was stated that the patients waiting admission numbered 130, while in the out-patients' department attendances were last year 1440 more than in 1929. Mr. J. P. Lockhart-Mummery said that during the past three or four years it had been possible to provide a certain number of private wards which had been greatly valued by the public, 93 patients having been admitted during the past year. It was hoped in the future to increase the number of those wards. Mr. Swinford Edwards, honorary consulting surgeon, who has been connected with the hospital for well over half a century, said that the new building was almost double the size of the old. Mr. J. Sandrey, the resident surgical officer, reported that the number of admissions for 1930 was 815. While there had been an increase of major operations there had been a relative decrease in the number of minor operations, owing to the recent introduction of successful palliative measures in the out-patients' department.

NON-SPECIFIC TREATMENT OF ASTHMA.

BY A. GUNN AULD, M.D. GLASG., M.R.C.P. LOND., D.P.H. OXF.,

FORMERLY VISITING PHYSICIAN, MILITARY HOSPITAL, MILE END; LECTURER ON CLINICAL MEDICINE AND PATHOLOGY, PRINCE OF WALES'S GENERAL HOSPITAL.

IN a paper[1] on asthma eight years ago I stated that it is commonly believed that in cases traceable to foods the ingested protein must pass unchanged through the intestinal wall, but that, excepting possibly in the sucking infant, there is no proof of such a leakage. We were taught by physiologists that normally only amino-acids are taken up from the intestine, but we now have proof that very small quantities of unchanged protein may be absorbed, in part by the lacteals. Mills,[2] in 1922–23, showed that when tissue fibrinogen was swallowed by man, it could be found in the blood from the finger-tip in two and a half minutes. This is now further proved by the Küster-Prausnitz reaction. It might be imagined that the inflow of minute traces of protein into the blood of sensitives would immunise the body against such proteins, but in many sensitive individuals it produces the opposite effect of activation.

Recent Work.

Oriel[3] states that one group of asthmatics manifested digestive failure and excessive decomposition of protein material in the intestines, with putrefactive bacteria. He treated this condition with glucose and ammonia; but we are told: "the most effective way to reduce putrefaction is to introduce into the diet certain carbohydrates so difficultly digestible or absorbable that they will exist in appreciable amounts throughout the length of the intestinal tract. Readily digestible carbohydrates, such as maltose, glucose, or sucrose, are ineffective, while lactose and dextrin are highly effective."[4] The implantation of aciduric bacteria normally inhabiting the intestines, such as *Bacillus acidophilus* or *B. bifidus*, has also been tried. The presence of carbohydrate protects protein material or protein degradation products from bacterial action. Thus the diphtheria and Shiga bacilli, which form toxins in protein medium, produce lactic acid in carbohydrate-protein medium and no toxin; the *B. coli* produces lactic acid and no indol.[5]

Oriel and Barber[6] have found that a proteose passed by the urine contains the antigen. This is an important fact, although the antigen cannot as yet be separated out. They also believe that "secondary antigens," the products of tissue damage resulting from the action of primary antigens on sensitised cells, particularly those of the liver, are "excreted in the urine and contained in the proteose." These secondary antigens may be a "denaturisation product of the primary antigen." "Is it not," they say, "likely that this substance is, so to speak, manufactured on the premises, a product of their own tissues?" We may call these secondary antigens "anaphylatoxin." It must be remembered, however, that if one calls the substance anaphylatoxin, it is usually regarded as being in the blood and tissues owing to the antigen having absorbed from them some substance which leaves them in a poisonous condition.

Whatever the antigen, it is excreted by proteose, and they administer very small doses of this proteose to the allergic patient. This is another proof that the proteose which I introduced in 1917 must act by desensitising the patient to the antigen.[17] Finding the proteose-peptone did not act well in certain cases, I made serum-peptone, to which a trace of agar was sometimes added. Karsner and Ecker[7] found that non-specific desensitisation with *homologous serum* in guinea-pigs was more effective than desensitisation with heterologous sera, which produced many deaths from anaphylaxis. Dale and Kellaway[8] found that homologous serum was well fitted for desensitisation in guinea-pigs. By adding proteose-peptone to the serum (and agar if desired) we get anaphylatoxin after incubation, which in small doses desensitises.

HOW SERUM PEPTONE IS MADE.

I now make the serum peptone differently.

After four hours of fasting, four or five ounces of blood are removed from the arm. This is very easily done. The arm is fairly tightly bandaged above the elbow. A short but rather wide needle is used, and its base passe through the rubber to touch the glass tubing in a very narrow cork to a large sterile tube. Two or three minutes should be quite sufficient to draw off the required bloo The tube is then rotated, and left at room temperatur until next day, when the serum is pipetted off into anothe tube. *To each ounce of the serum* 1·5 g. *of Armour's No.* peptone is added, and sometimes a trace of agar (0·006 g. which has been well boiled. At the same time about te drops of chlorofrom (=♏ 3–4) are also added. The tube i *then put in the incubator at* 37°–40° C., *and left at tha* temperature for two to three hours, when the heat is turne off. *It is left in the incubator until next day,* when th insoluble part of the peptone will be seen right at the bottom and a perfectly clear fluid above. This fluid can be poure or pipetted off. It is slightly alkaline and contains som anaphylatoxin.

Serum with agar alone was tested on guinea-pigs by Dr. Anrep, and he found that 2 c.cm. injected into the femoral vein caused considerable shock, whil 5 c.cm. of plain serum did *not* affect them.

The Treatment.

When a large number of proteins are scratche on the skin in groups of five, 16 scratches will giv the results of 80 proteins, and sometimes a positiv reaction is found, especially in children and young adults, to one or more proteins. I have had several cases wherein the withdrawal of these resulted i great benefit. The patient's food must be thoroughly masticated. If not completely digested, some of it may pass unchanged through the bowel wall into the system, and set up disturbance. Before treatmen is commenced the scratch test should be made wit peptone on the arm, using concentrated peptone solution. If the response is slight, use the peptone solution more freely in treatment; if considerable use it cautiously. Some say that peptone treatment is dangerous and must be used with great care. I always use care, but after thousands of injections have never found it dangerous, even in young children, who take it very well. Some America physicians have stated that the peptone made u in their own laboratories is much superior to tha obtained in the market.

Begin with ♏ 5 of the 5 per cent. solution o peptone and go up by ♏ 3 twice a week. Th injection, in adults at least, should usually be mad in the vein, and a quarter of a minute allowed t elapse between each ♏ 3 given. Go up to 2 or 2 or 3 c.cm. if suitable. In some patients a maximu dose of ♏ 20 is sufficient, continued for some tim Intramuscularly give 7·5 per cent. solution. after 10 or 12 injections twice a week there is bu little effect, produce a slight reaction in the patien This may require 4 c.cm. of serum peptone. Ea patient differs, and a certain percentage derive litt benefit from the treatment. Begin the seru peptone treatment with about ♏ 10, going up

♏ 5 each time until 3 c.cm. is reached. If the patient improves, say at 2 c.cm., continue at that dosage for some time. Usually it is best to begin with serum peptone after plain peptone has been tried. Novy and his associates found that guinea-pigs' serum added to the peptone mitigated the effects of the latter. When patients are nervous about the taking of their blood, give them the serum peptone from another healthy person.

I have had a good many patients in whom, after treatment, the asthma has been either entirely or practically absent for three years. In a few it has been absent many years, but it is difficult to say whether or not these have undergone a natural cure. Sometimes, after three or four courses of treatment given from time to time for a year or a year and a half, the asthma will cease.

The following case will illustrate this:

A patient, female aged 52, Londoner, consulted me in July, 1925. Her father had brothers with asthma. It began with her at the age of 16, and has practically continued ever since. Cannot sleep. Uses an inhaler every night. No expectoration. The fit passes off quietly. She had a sensitive dermographic skin. She first got 14 peptone injections, but was no better. She was resolved to go on, and had serum peptone made, getting two injections a week when she got great relief. After two months the asthma began again, and she again got 8–10 doses of serum peptone. The asthma again ceased for some months. She had two further courses of serum peptone at intervals. Since November, 1926, she has remained quite free from any symptoms of asthma.

As has been mentioned, sometimes ♏ 20 of the peptone solution is as high as it is necessary to go. A rather remarkable case was sent to me by Dr. A. H. Watt, of Johannesburg.

The patient, a male aged 67, had suffered greatly for many years. He had had many treatments in different parts of the world and was last under Storm van Leeuwen in Leyden. He was tested and found sensitive to moulds. Prof. van Leeuwen treated him for this by inoculation, but without effect. He then put him in one of his allergen-free chambers, where he considerably improved. On returning to Pretoria he erected an allergen-free chamber in his own house, but received no benefit from it. I suggested peptone alone, but as he said he got a big injection of it into the gluteal region from a doctor in Pretoria which made him very ill, he was loth to have it done. He consented, however, and he also had small doses of ultra-violet rays. He got so well that, instead of going to Mont Dore as he had intended, he went to Scotland for a change. On his return he had more injections but not even up to ♏ 20. He also had light rays. He was highly satisfied, and returned to Pretoria. He told me that he had always carried adrenalin with him, and at night had to have ephedrine and eupnine beside him.

The next case I mention was treated very differently.

A male, aged 42, was sent to me last summer by Dr. J. A. Delmege, of Weaverham, Cheshire. He had a Government appointment in West Africa, but was pensioned off in 1925. He got a severe cold which he could not shake off, and a terrible cough, so that he was obliged to sleep away from everyone else. On returning to this country, he took a dose of aspirin, which nearly killed him, and it brought on asthma. He had to go to a nursing home with asthma and bronchitis until 1928, and in that year had many polypi removed from both nostrils, which made him no better.* He came to me in a very feeble state, could only walk with difficulty, and had much asthma and great cough. His chest expanded 1¼ in. and there was considerable emphysema. He showed no reaction to 60 proteins. He had serum peptone for 16 doses. From the sixth to the twelfth injection he had anticatarrhal vaccine subcutaneously for his bronchitis, from ♏ 4 up to 1 c.cm. He had ultra-violet rays, 16 exposures up to seven minutes each for the chest and back. He also had six injections of his own blood subcutaneously, three of 5 c.cm. and three of 10 c.cm. At the end of the treatment he was a new man. His asthma had gone; he was quite fit and he could walk considerable distances. His chest expansion had risen from 1¼ to 4 in.

There was no real emphysema. It was rightly stated by Hurst [10] that emphysema occurring in asthma may be deceptive. After staying the summer and autumn here the patient wanted a change for the winter, and I advised him to visit Switzerland; to choose a low altitude at first on account of the bronchitis, but if this improved to go higher. He had a very low blood pressure. He went to Montreux (1263 feet), then to Château-d'-Oex (3180 feet), and lastly to Montana (5000 feet), where he got on splendidly. His symptoms returned in the spring, however, to some extent, and he was treated with small doses of tuberculin which did very well with him.

I may mention one other case which is remarkable in demonstrating that the vagus may show great irritation in asthma.

The patient, a male aged 28, was sent to me by Dr. Ross Taylor, of Eastbourne. He was a healthy looking young man, very spare, and, when well, usually had a strong appetite. Some of his relations have hay-fever. He had suffered from asthma off and on for nine years and was negative to all tests. He had no emphysema. When an attack of asthma began he became sick and often vomited bile; his bowels had a rapid and severe action, usually with diarrhœa, and he passed large quantities of practically colourless urine. All these symptoms showed a violent stimulation of the vagus. The asthma came on from time to time and he is quite well in the intervals. We cannot tell what toxin attacked the vagus (if it was a toxin) but it may have been autogenous. I began treatment by giving glucose and insulin 5 units twice a day. I continued this for some time, but it produced no benefit. I then gave him 20 injections (intravenous) of peptone and serum peptone and also tried him with mixed coliform vaccine, as recommended by Coke. He also had several blood injections up to 10 c.cm. He got much better, but after I gave him MacLean's alkaline mixture * [11] he said he thought it did him great good, and he took it for a long time. He also had 16 ultra-violet light treatments up to seven minutes for chest and back. He remains quite well.

It is possible that the alkaline mixture had considerable effect in mitigating the toxin. But this must be exceptional, for I tried a number of asthmatics with fairly large doses of alkali for a fortnight and then with fairly large doses of nitrohydrochloric acid for a fortnight, and they nearly all replied that they were better on the acid, probably owing to stimulation of the liver.

Results in Germany.

The peptone injection treatment of asthma and other allergies is making great headway in Germany. On this account Herr Witte, in addition to his widely known peptone (which is used chiefly for bacterial growth), has, in conjunction with a German University, produced a new peptone for injection, which he says is much less toxic than the ordinary peptone. The fatal dose of the new peptone lies between 80–100 mg. on a 100 g. rat, as against a dose of 40 mg. of the ordinary Witte peptone, and there are also clinical differences. Herr Witte has kindly sent me a quantity of this new peptone for trial. Last January he named it "peptone Witte special 30." Only a few German authorities have information about it. I have been testing a 5 per cent solution, but its full trial will take time. It is very successful, producing no irritation, subcutaneously or intramuscularly, and is quite satisfactory intravenously, but in the latter instance must be used rather cautiously. It contains the various proteoses, is very soluble in water or saline, and makes a good serum peptone. Herr Witte is pleased that "peptone Witte special 30" should be introduced to the profession in England.

Many German physicians have more recently described at great length their experience with peptone. Lately Drs. Petow and Wittkower [12] (with Prof. W. His, of Berlin) gave a minute description of the desensitising therapy of bronchial asthma. They say that the value of the skin test trials for recognising specific allergens that cause asthma is, in their opinion, apparently over-estimated for the therapy of asthma. Without knowledge or consideration of a specific allergen, good results are obtained with non-specific desensitisation. With the lack of knowledge of the specific allergen the non-specific desensitisation with peptone or tuberculin gives approximately good results. They tried 176 cases, and with peptone the good results were 60 per cent., and with tuberculin 50 per cent. The number of patients treated with peptone was 41, and 24 per cent. were free from asthma; 27 per cent. were greatly better; 29 per cent. were considerably better; and 20 per cent. were not improved. In the case of tuberculin, the number treated was 54, of whom 26 per cent. were rendered free of asthma, 26 per cent. were greatly better, 32 per cent. were considerably better, and 17 per cent. were not improved. Another very recent and long paper by Dr. Eric Urbach [13] (with Prof. W. Kerl, in Vienna) appears in the same journal. He states that Luithlem substituted for the Witte and Armour peptones a mixture of animal and vegetable peptones, with much better results, a combination which I had first recommended.[14] I have not used this combination for some time, but it may be worth while attempting it again.

---

* Formulæ from Allen and Hanburys.

Prof. Umber,[15] of Berlin, states that "long years of clinical experience coincide completely with the results of Petow and Wittkower." "In my clinic," he writes, "we use almost exclusively the subcutaneous treatment with peptone, not only for asthma, but also for allergic diarrhœa, urticaria, &c. We are extremely satisfied with this method of non-specific desensitisation, having practised it for five years, and it is highly advisable to recommend same to practitioners." Dr. Loeb [16] states that "in asthma, after peptone injections, in about one-third of the cases the attacks have quite subsided, so that the patient is practically healed. In other cases the attacks have much diminished. Very effective results in allergic diseases have been reported by numerous authors."

From the foregoing remarks it will be seen that non-specific treatment must enter largely into that of asthma. Specific treatment is best when the allergen is discovered, which is not often, but even in this case it is better to use also the non-specific for some time, as the patient may fall a victim to another allergen. In fact, most patients who suffer from one allergen also suffer from others. Peptone and serum peptone are probably the best, as they cause no anaphylaxis and are suitable for all cases, however much they differ, though in some cases they fail. As the work of Oriel has shown, the proteose of the patient takes up the allergen and excretes it, which alone is a sufficient reason for the injection of peptone.

TORBAY HOSPITAL.—Last year there were 1941 in-patients, an increase of 273. Their average stay was 22·08 days and their average daily cost was 8s. Notwithstanding that the ordinary expenditure increased by nearly £2000, reaching a total exceeding £17,300, the hospital paid its way, thanks to an increase of over £3300 in the ordinary income. What the report describes as "this really wonderful result" is mainly accounted for by the growth of the contributory scheme which last year increased by £2822 to £5475.

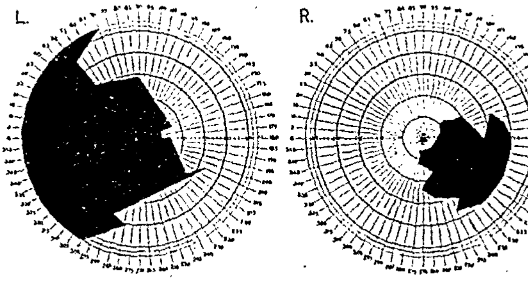
X RAY TREATMENT OF PITUITARY DISEASE.

BY FFRANGCON ROBERTS, M.D. CAMB.,
M.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE X RAY DEPARTMENT,
ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

THE pituitary body perhaps appears at first sigh to be unfavourably situated anatomically for X ra, therapy. In two important respects, however, it position is singularly fortunate. First its centra position no more than 8 cm. from the temples and forehead allows it to be readily subjected to cross-fire radiation from several directions. Secondly, it i surrounded on all sides by nervous and bony tissues which, themselves highly resistant to radiation provide an ideal material for the productio of secondary scattered rays which considerabl supplement the primary rays issuing from the tube The one possible disadvantage, the risk of depilatio of the scalp, can be avoided by suitable adjustmen of the dose and even if depilation occurs it must b accounted a small price to pay for alleviation from serious pituitary disease.

To Béclère [1] belongs the credit for having in 190 been the first to irradiate the pituitary. One o his patients was alive 20 years after treatment wa begun. Schlesinger [2] found that subjective symptom and somatic changes in acromegaly were improve and also got good results in diabetes insipidus Nobécourt, Duheim, and Bize [3] reported considerabl though only temporary improvement in a boy of 7 who had lost his sight through a tumour of the sella. Vision was in some measure restored, headach disappeared, and vomiting ceased. Nemenov and Jugenburg [4] obtained improvement in the 18 cases of pituitary disease which they irradiated. Headach disappeared and in some cases vision showed remar able improvement, those who at first were almos blind being subsequently able to read and do fin hand work. While their most successful cases wer those of adenoma of the anterior lobe, they clai improvement also in dystrophia adiposo-genitali Cerni and Gejnisman [5] found similar results regards acromegaly but less constant improveme in dystrophia adiposo-genitalis. Where the ophthalm symptoms were already advanced there was permanent improvement. Magnus [6] out of 34 cas obtained the best results in benign adenomata the anterior lobe. The results were less good acromegaly, endotheliomata, and cysts. Hamann found six out of ten cases favourably influenced regards vision and the general condition. Griffith reports enlargement of the fields and disappearan

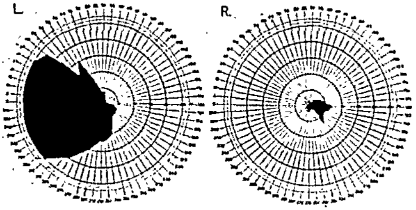
FIG. 1.



Fields of vision Sept. 18th, 1929.

of symptoms in a case showing bitemporal central scotomata following X ray treatment which was administered by Béclère. Béclère[9] considers that adenomata of the anterior lobe show the best results and since these are by far the commonest tumours, X ray treatment should in all cases be tried first. He quotes Cushing in support of this view. Sgalitzer[10] finds that benign tumours need less treatment than malignant. Cystic cases are refractory, while dystrophia adiposo-genitalis is rarely benefited.

FIG. 2.



Fields of vision June 7th, 1930.

There is therefore a consensus of opinion that adenomata of the anterior lobe are readily influenced by X rays and that in other conditions improvement is less certain. The comparative failure of X ray treatment in adiposo-genitalis is not surprising in view of the fact that this condition is generally believed to be due to atrophy and not to hypertrophy of the pituitary.

As regards dosage, most of the radiologists quoted above give about 80 per cent. of the erythema dose at 180 k.v. (kilovolts) heavily filtered through the temporal and frontal areas. It is significant however, in view of the general advocacy at the present day of high voltages, that Béclère employs a peak voltage no higher than 100 k.v.

RECORD OF CASE.

A youth, aged 19, height 5 ft. 8 in., weight 11 st. 2 lb., a butcher's assistant, was admitted to Addenbrooke's Hospital on July 26th, 1929, under Dr. G. S. Haynes. He gave a history of having injured his head through a bicycle accident three years previously. He said that he had no energy and wanted to sleep all the time. He was always hungry, ate ravenously, and was rapidly putting on weight. He complained of headache which was worse in the morning and aggravated by stooping. There was no vomiting, no polyuria, no sign of acromegaly. Vision had been failing for some time and was now very defective. Bitemporal scotomata were found in both eyes. (See Fig. 1, and note by Mr. Cooke below.) Radiographic examination showed irregularity and great enlargement of the sella turcica with erosion of the clinoid processes. (In Fig. 3 the appearance of the sella is reproduced in its actual size.) It was therefore clear that the condition was due to pressure upon the optic nerves by a tumour of the pituitary.

Treatment with X rays was begun in August, 1929. Once a fortnight 80 per cent. of an erythema dose at 180 kv., filtered through 0·5 mm. of copper and 1 mm. of aluminium, was given through the temporal fields alternatively, the field being circular with a diameter of 5 cm. After two applications vision began to improve, headache disappeared, the patient was less sleepy and his appetite had diminished. Examination of the fields of vision at intervals showed a steady and well-marked diminution of the right scotoma and a slight improvement in the left. The condition on June 7th, 1930, is shown in Fig. 2. Subsequent X ray therapy produced no further improvement in the fields owing doubtless to the fact that some of the optic fibres were permanently atrophied.

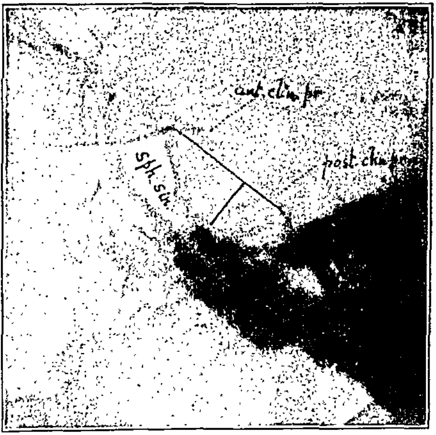
Biochemical investigation (Dr. C. G. L. Wolf) revealed in March, 1930, an increased sugar tolerance which became less in the following seven months. Basal metabolism was +4. Meanwhile all symptoms other than ocular had disappeared and vision had so far improved that during the summer of 1930 the patient was able to brave the perils of the streets on an ice-cream tricycle. In December a slight relapse occurred but this readily yielded to a few doses of X rays. At the present time (February, 1931) the patient feels perfectly well, and is fit for work but unfortunately is unable to find any.

The readiness with which this patient has responded to X ray therapy makes it probable that he is a case of simple adenoma of the pituitary. The main interest in the case, apart from the material improvement, lies in the fact that repeated examination of the fields of vision has provided an accurate gauge of the effect of treatment.

NOTE BY MR. ARTHUR COOKE.

This patient's vision was tested in April, 1927, and found to be 6/6 in each eye with a small degree of hypermetropia. In November, 1919, R.V.=6/18; L.V. less than 6/60. Well-marked bitemporal scotomata were present measured on Elliot's scotometer and recorded in Fig. 1. This condition pointed to an intrasellar pituitary tumour pressing on the optic chiasma. The remarkable improvement in the scotomata after six months X ray treatment is shown in Fig. 2. Vision improved to R. 6/6, L. 6/60. Reading small type was very slow at first owing to the scotoma in the right eye being equivalent to a partial right hemianopia, where the letters can only be picked up separately as if one were reading with a moving sheet of paper always covering the letters to the right. This has improved so much now that reading proceeds at a normal pace.

FIG. 3.



Lateral radiographic view of the sella turcica. The black lines show its length and depth.

CLINICAL AND LABORATORY NOTES

NOVASUROL AND HEART FAILURE IN GRAVES'S DISEASE.

By J. R. Armstrong, M.B. Camb.

The following case of Graves's disease is of interest for several reasons. In the first place the disease was of long standing and, although very pronounced, was not progressing; the patient suffered relatively little inconvenience and was able to live a quiet life in comparative comfort. In April, 1930, she suffered from an attack of acute bronchitis, and from this date her trouble really began. With the advent of bronchitis she developed auricular fibrillation, and alarming œdema rapidly followed, which was so acute and extensive that I regarded the condition as almost hopeless. The patient was treated with digitalis, diuretics, and novasurol in particular, and the result obtained with the latter drug is recorded, as it appeared to be of particular interest. The subsequent history of the case is also of interest in view of the return of the heart failure, the sudden death, and the post-mortem findings.

ACCOUNT OF A CASE.

A woman, aged 53, who came under my care in November, 1929, had suffered from exophthalmic goitre of considerable severity since 1919. She was very emaciated, was 5 ft. 2 in. in height, and had averaged 7 st. 7 lb. in weight. Exophthalmos and tremor were marked, and in fact all the classical signs of Graves's disease were present. Until April, 1930, she had been walking about without discomfort, her weight had been stationary, and she had been under regular observation. At the end of April, however, she developed acute bronchitis and was confined to bed for three weeks, at the end of which time, although the chest condition was satisfactory, the pulse-rate suddenly increased and the general symptoms became aggravated. Œdema of the ankles was first noticed and spread as far as the knees, the patient improving after treatment with rest and digitalis.

During the period of convalescence, however, while the chest continued to improve, the heart began to dilate, and on May 28th auricular fibrillation was first noticed. Œdema of the lower limbs rapidly followed and quickly became generalised, the abdomen becoming acutely distended and the urinary output continuing to fall. Dyspnœa was not conspicuous, the chest was full of moist râles, and the patient continually cleared her throat of mucus and brought up small quantities of frothy sputum. As her condition was somewhat desperate, venesection was performed and several ounces of blood removed, and digitalis was given in ʒi doses three-hourly up to half an ounce. On the 29th novasurol, 0·5 c.cm., was given intramuscularly and the urinary output, which had hitherto been approximately 30 oz. per day, rose on the 29th to 64 oz. and on the following day to 70 oz. Digitalis was now given in smaller doses, together with ammonium chloride grs. 15 four-hourly. On June 1st the pulse-rate was 118, the urinary output measured 32 oz. and 1 c.cm. of novasurol was given, and in the next 24 hours 58 oz. of urine were passed. On the subsequent days—namely, June 4th–8th—the daily urinary output only averaged 34 oz. On the 9th novasurol, 0·5 c.cm., was given and followed by the passage of 72 oz. of urine in the next 24 hours. On the 13th a further similar dose was given and the patient passed 80 oz., the pulse-rate falling to 98. By this time her condition had considerably improved and the ascites had almost completely disappeared. The upper limbs were free from œdema, the voice was no longer husky, and swelling was confined to the lower limbs. A further dose of novasurol was given on the 16th and the patient passed 64 oz. of urine; thereafter steady progress was maintained. On July 7th she was free from œdema, the pulse-rate was 76, and she was able to walk short distances. On the 14th she went to the seaside to convalescence and I heard no more of her until August 23rd, when a relapse occurred. On August 25th the patient died, and on the 27th I made a post-mortem examination.

The body was emaciated, the abdomen discoloured and enormously distended, and œdema was present from the legs upwards to the tissues over the lower ribs. Several pints of free fluid were present in the abdomen, and free fluid was also found in the pleural cavities. Examination of the internal organs revealed an enormously large and vascular thyroid, œdema at the bases of the lungs, congestion of the liver and kidneys, and an enlarged heart weighing 26 oz. The latter showed dilatation of all chambers and hypertrophy of the right side; the cardiac muscle appeared to be healthy and the coronary arteries normal. The aorta also showed no signs of disease. Death had occurred from heart failure.

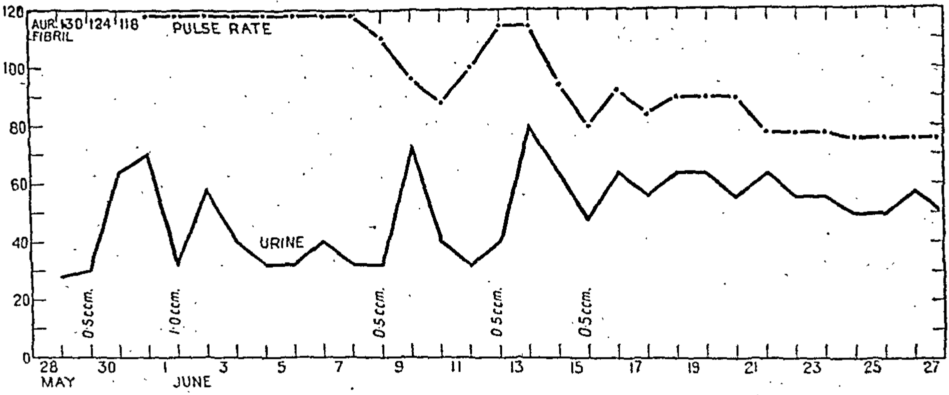

Chart showing decline of pulse-rate and increase of urinary excretion (in ounces). The decimal figures show the amount of novasurol given (in c.cm.).

Apart from the usual findings in such a case, the clinical interest lay in the diuresis following injections of novasurol which occurred earlier in the history, and in the fact that with this particular case 0·5 c.cm. was as effective as 1·0 c.cm.

ACTION OF THE DRUG.

Novasurol appears now to have obtained a definite place in the treatment of cardiac disease with obstinate œdema. Since its introduction by Zeiler, in 1917, for the treatment of syphilis, its therapeutic value as a diuretic was first observed by Saxhl and Heilig, and it has recently been used with success in America by Keith, Barnes, and Whelan, who have shown that it is more effective if combined with a low salt and low fluid intake and ammonium chloride in large quantities.

Nonnenbruch, by experiments on medical students has shown that in normal persons after the administration of 2 c.cm. of a 10 per cent. solution of novasurol there is a great elimination of sodium chloride and water, and that the drug resembles theophyllin in this respect. The effect of the drug, he found passed off in 10 to 12 hours, when compensation was effected by retention of water and sodium chloride. The superiority of novasurol over theophyllin however, is shown by the fact that novasurol still acts on the organism which has been rendered poor in water and sodium chloride by previous salt-poor days or by sweating; theophyllin does not act in these circumstances. This work has also been confirmed in America by Marvin who, although sceptical of the enthusiastic statements in the literature about novasurol, yet found that in those cases of heart disease which were characterised by large amounts of œdema and which had no evidence of renal disease, diuresis followed the injection of novasurol when it had ceased after full digitalisation. The same applied to cases treated with theophyllin, novasurol always causing a further diuresis whilst the converse was rarely, if ever, obtained. The results in these cases were determined by measurement of the urinary volume, reduction of the œdema, and changes in body-weight.

East and Bain recommend the use of novasurol in cardiac failure when treatment with rest and digitalis has first been tried and when massage and xanthine derivatives have been employed without success. In the case here described this was the procedure adopted, but it was not until novasurol and ammonium chloride were given that any great difference in urinary output occurred. The mode of action of the drug is not yet clearly understood. It is known that small doses of calomel have a diuretic action, and this is supposed to be due to the irritating action of the mercury on the renal epithelium. The variable absorption of calomel, however, makes it unreliable for this purpose, and this may be why the drug fell into disuse and neglect after it had been previously introduced in the treatment of cardiac failure in the latter part of the eighteenth century. In 1886 Jendrassik reintroduced it, and it has been used ever since. Diuresis has been shown by Flexseder to occur in rabbits after the administration of mercurials, and this observer considered that mercury lessens the absorption of food-water from the small intestines and that water reaches the large intestine in excessive quantities and is absorbed, then acting as a diuretic. It has been pointed out, however, that this does not explain the absorption of exudates.

Novasurol, which contains 33·9 per cent. of mercury, is thought by Saxhl and Heilig to diminish the affinity of tissue colloids for water and chlorides, which accordingly pass into the blood stream and temporarily dilute it. The glomeruli filter out chlorides and water together with the other constituents of the urine, but these instead of being normally reabsorbed by the tubular epithelium, pass out, reabsorption not taking place owing to diminished affinity of the latter. Crawford and McIntosh found that after the administration of novasurol dilution of the blood occurred, that an increase in the chloride percentage preceded the diuresis, and that both of them fell during the diuresis.

The administration of adequate doses of ammonium chloride or ammonium nitrate is advocated by Willius, as he found that satisfactory results could not be obtained otherwise. This has been confirmed by other observers. After the administration of ammonium chloride two characteristic changes occur in the blood plasma, one in the carbon dioxide combining power and the other in the chlorine content, and it has been shown that the urine during diuresis always shows a hydrogen-ion concentration below 6·0, varying from 5·8 to 4·6, the urine becoming decidedly more acid in two to six days after the administration of ammonium chloride.

Keith has shown that when the chlorides in the blood are low, mercury compounds fail to produce *diuresis*, and he considers that the greater and more constant diuresis obtained by the combination of novasurol with ammonium chloride is due to the increase of the chlorine content in the tissues rather than to the decrease in the alkali reserve. Whatever may be the correct explanation, however, it appears that novasurol, when combined with ammonium chloride, is decidedly more effective than when given alone, and that the combination of the two drugs frequently exerts a powerful diuretic action in cases where other measures have proved unsuccessful. In this case no toxic symptoms were observed after the administration of the drug, and the patient experienced no pain over the sites of the injections.

INEFFICACY OF LIVER TREATMENT IN ESSENTIAL THROMBOPENIA.

BY L. J. WITTS, M.D. MANCH., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, GUY'S HOSPITAL; WILL EDMONDS RESEARCH FELLOW.

THE changes in the blood-platelets in pernicious anæmia after liver therapy have been carefully studied by Nittis.[1] The platelets are much diminished in the active phase of the disease. On treatment with liver they increase in numbers, reaching a level higher than normal, after which they decrease to normal values. The highest count usually occurs several days after the maximum reticulocyte crisis. There is no gross correlation between the increase in numbers of the platelets and that of the erythrocytes, the leucocytes, or the reticulocytes. Cramer[2] in 1929 suggested the treatment of essential thrombopenia by liver. This suggestion was based not only on the increase of platelets in pernicious anæmia so treated, but also on Cramer and Drew's experiments[3] on rats, in which the production of platelets was stimulated by vitamin A and ultra-violet light. Successful treatment of essential thrombopenia with liver has been reported by Mondon,[4] Holboll,[5] Jacob and Clapperton,[6] and Box and Massingham.[7]

In the present paper I am reporting the results of liver treatment in five carefully chosen chronic cases of essential thrombopenia. None was benefited, and in my opinion liver is of no value in essential thrombopenia. The published records of successful cases, to which I have referred, provide no evidence that the liver in any way affected the patient's recovery. All were isolated acute cases, and it is well known that the majority of cases of acute essential thrombopenia spontaneously get better. Proof of a therapeutic action of liver in acute essential thrombopenia would necessitate a large series of cases, and an equally large series of controls. Recently I had an acute case under my care, and was careful that no specific treatment should be given. The patient recovered rapidly and completely.

A boy, aged 3, developed *a boil on the left side of the* neck. Three weeks later he had a coarse purpuric eruption, one or two of the patches breaking down and ulcerating, and his nose bled. The spleen was not palpable. The blood count was: red cells, 4,470,000 per c.mm.; white cells, 8100; hæmoglobin, 74 per cent.; colour-index, 0·8; the differential count was normal; platelets were reduced *to 12,000* per c.mm.; *the bleeding* time was much prolonged. The boil was incised, but there was no other treatment beyond ordinary nursing care. A week after admission the platelets had increased to 23,000; a month after admission they were 250,000 per c.mm., and the bleeding time was normal.

Few maladies can inspire us with a more urgent desire to institute active treatment than acute essential thrombopenia. Few are more liable to the fallacy of *post hoc, propter hoc.* It is undesirable that in so brief and so dangerous an illness the physician should rely on a therapeutic measure of unproved worth. It is clear that the value of liver is at any rate not proved in acute essential thrombopenia, while the following cases conclusively show that it has no action in chronic essential thrombopenia.

CASE 1.—A woman, aged 54, has suffered from recurrent attacks of purpura and epistaxis since she was 9 years old. She was admitted to hospital after an epistaxis lasting 12 hours. There were several purpuric spots, and she bruised very readily. The spleen was not palpable. The only abnormality in the blood count was a diminution of the platelets to 27,000 per c.mm. She was treated with liver extract for four months without any demonstrable effect on the platelet count, and another severe epistaxis then occurred. No change occurred on omitting the liver treatment.

CASE 2.—A man, aged 50, has been attending Guy's Hospital with essential thrombopenia and secondary anæmia for 25 years. He is hardly ever free from slight epistaxis and melæna, but tolerates his disability very well and steadfastly refuses splenectomy. The bleeding time is much prolonged, and the spleen is easily palpable. At no time have I been able to find more than 15,000 platelets per c.mm. He was treated with liver extract and whole liver for four months without improvement.

CASE 3.—A man, aged 20, was one of a family of five children, three of whom have suffered from essential thrombopenia. A sister died from hæmorrhage at the age of 5. He had suffered from epistaxis and melæna for 15 years. He had never had purpura, but bruised readily. The spleen was not palpable, but the bleeding time was prolonged. His platelets were 30,000 per c.mm. He was treated with liver extract and whole liver by mouth for three months. The platelets underwent no improvement, and he had two severe epistaxes. He was readmitted to hospital for splenectomy, and died 36 hours after operation.

CASE 4.—A boy, aged 7, brother of the above, has suffered from bleeding from the gums and purpura since he was 4. His platelet count fluctuates between 10,000 and 90,000 per c.mm. He has had rather irregular treatment with liver without improvement.

CASE 5.—A man, aged 37, developed a severe secondary anæmia and thrombopenia, with purpura, hæmorrhage from the gums, and small cerebral hæmorrhages, after treatment of a chronic prostatitis. He was at first thought to have septicæmia, but improved greatly with a series of transfusions. Thrombopenia and secondary anæmia persisted. He was treated for two months with liver and liver extract, but the platelet count was unchanged and small hæmorrhages were continually present. I am unable to decide whether he is suffering from essential thrombopenia or a chronic aplastic anæmia.

In all five cases the platelets fluctuated in numbers during the liver treatment, as they do in untreated cases, tending to rise a little after hæmorrhage and sooner or later falling again below the critical level. In no case was there any permanent increase in the number of platelets, and all bled during the liver treatment. One must conclude that liver has no specific power to increase the number of platelets, and that the rise in platelets which accompanies liver treatment in pernicious anæmia is secondary to the improvement in the functions of the marrow on the resumption of normal erythropoiesis.

A CASE OF DISSECTING ANEURYSM.

BY J. L. SWANSTON, M.B. EDIN.,

LATE HOUSE SURGEON, PETERBOROUGH AND DISTRICT MEMORIAL HOSPITAL.

AN engineer, a well-nourished and well-developed man aged 54, was admitted to hospital with the following history. In the morning he was carrying a pail of coals when a sharp cutting pain in his stomach made him sink to his knees and then on the floor. The pain started in his back and went round his stomach. It was continuous and severe—he writhed in agony. He felt sick, but did not vomit. He had had a sharp pain in his stomach 14 days ago while working. He had always been active and healthy. He had no urinary or biliary symptoms. Appetite was good, no indigestion, bowels regular and opened that morning.

Condition on admission.—Temp. 96·8° F., pulse-rate 60, respirations 28. *Patient writhing in agony, groaning and* short of breath. Pain all over *stomach.* Abdominal excursion, with *respiration*; large. umbilical reflex absent, slight hyperæsthesia all over. Percussion tympanitic except in right flank, where dull. Liver dullness sixth space to costal margin. Abdominal musculature very rigid, despite deep breathing. Tongue dry and slightly furred. *Pupils equal, reacting briskly to light*; knee-jerks, left, +; and right, + +. Respiratory system: slight dullness right side; vocal resonance +, vesicular breath sounds; no accompaniments. Cardiac system: apex-beat, sixth space, 4½ in. out; sounds closed. Urine: no sugar, albumin, pus, or bile by ordinary tests.

It was decided to operate, but a mid-line incision failed to reveal any abnormality *and the abdomen was closed.* *The patient's condition* remained unchanged and pain was controlled by morphia. On the following afternoon he "was feeling much better" but after a wash he suddenly became pale and dyspnœic and died.

At *autopsy* the right thoracic cavity contained one gallon of clotted blood which was displacing the lung and heart well over to the left side. The *posterior mediastinum* contained extravasated blood and the root of the lung showed a tear posteriorly and the pleural surface was otherwise healthy. The alimentary system was healthy *and the stomach* very large. The extravasation in the posterior mediastinum was seen to extend down the spinal column along the aorta and common iliacs to their bifurcation. The aorta admitted no more *than the* tips of tw fingers at any part. *It* had atheromatous changes most marked in the abdominal portion. At the junction of the arch and thoracic portion was a T-shaped rupture of intima *and media coat.* About the middle of the abdomina portion was a second rupture; it was 2½–3 in. long and i the long axis of the aorta. The intima and media coat were separated from the tunica externa by clotted bloo from a few inches *below* the lower rupture to the upper on Extravasated clotted blood was abundant around the aort but the point through which *it* had passed the tunic *externa* was not found.

The heart was enlarged and dilated. The pulmona and aortic valves were competent, with slight thickeni of *the* mitral cusps. All *the arteries had thickened* wal The kidneys showed a fine degree of chronic interstiti nephritis. Lungs and liver were congested.

This case brings forward the difficulty in diagnosi a dissecting aneurysm. The sequence of events ca however, be easily followed. A sudden slight increase in the blood pressure caused the aorta to stretch, but the inner walls being calcareous and less distensible than the elastic outer wall, ruptured at the site of greatest strain—outside of the bend (arch) and the large area (abdominal portion), the pressure of the blood then tracking into and through the walls, and eventually finding a spot to burst into the pleural cavity at the root of the lung. The abdominal pain and rigidity was referred from this area of extravasating blood, the sudden hæmothorax being the immediate cause of death.

The interesting point is the resemblance the case had to a perforated gastric or duodenal ulcer. I consider the following points were of greatest diagnostic value: (1) Site of origin of pain—viz., in the back and not epigastrium. (2) There was no period of reaction due to the dilating peritoneal fluids or shutting off by omental adhesion, &c. (3) Respiration was of large excursion, and not short and jerky as in peritonitis.

MEDICAL SOCIETIES

TUBERCULOSIS ASSOCIATION.

At a meeting of this society held at Oxford from Thursday, March 26th, to Saturday, the 28th, the Thursday session was chiefly occupied with a discussion on Stereoscopic Radiography (see p. 822). At the morning session on Friday a discussion on the

Natural Processes of Healing

in pulmonary tuberculosis was introduced by Dr. M. Jaquerod, of Leysin. Rest, hygiene, and diet as methods of treating tuberculosis were now, he said, being relegated to a secondary position. All treatment tended towards collapse therapy, and those who believed in inducing an artificial pneumothorax early were in the ascendant. Radiology had rendered invaluable service to the study of the processes of healing. Apart from certain acute and generalised forms, pulmonary tuberculosis might be regarded as a chronic illness from the beginning, and this conception should be the basis of any description of the processes of healing. Virchow's view was that all lesions of pulmonary tuberculosis necessarily originated from miliary tubercles, but there were in the neighbourhood of chronic and fibrocaseous foci congested and simple inflammatory areas which nowadays were regarded as the antecedents of chronic lesions. This conception of the pneumonic or inflammatory nature of tuberculous lesions originated in the minds of two English pathologists, Wilson Fox and Green, in 1873. Dr. Jaquerod considered that in this stage of the disease the tubercle bacilli remained on the surface of the mucous membrane between the epithelial cells, in the alveolar and intercellular spaces, and that their destruction and elimination was therefore rendered much easier. It was only when these lesions did not heal that new tissues were produced.

The question, "How recent is the disease?" was therefore a matter of primary importance. It was necessary to distinguish the non-allergic type found in childhood from the lesion of a patient already sensitised by previous contact with tubercle bacilli. In the former the pulmonary lesions might regress and heal by resolution, or pass the non-allergic phase and become serious. In the latter the inflammatory reaction was broncho-pneumonic, and might end in cavity formation. This cavity was, however, different from that of chronic disease; its walls were not well-organised pyogenic membrane, but simple inflammatory tissue. It might heal by resolution without leaving any apparent scar. A third form, *chronic fibrocaseous tuberculosis*, was a complicated process leading to fibrous transformation of the lung. The first two forms always existed before the third, and it was in these that treatment had its best chance of success.

DISCUSSION.

Dr. T. Campbell emphasised the possibility of primary infection in adult life, and regretted the concentration of attention on childhood infection.—Dr. W. C. Fowler regarded the regeneration of lung tissue as in the nature of a compensatory emphysema.—Dr. A. J. Morland pointed out the curious fact that early cavities were absolutely spherical. He thought this was brought about by the retention of air under pressure owing to the valvular opening. When the air was liberated the cavity might collapse and practically disappear.—Dr. Burrell thought Dr. Morland's suggestion might explain the existence of pleural rings, which did not fill with lipiodol or collapse with artificial pneumothorax.—Dr. G. T. Hebert adverted to Mitchell's theory of an air sac as an explanation of pleural rings or annular shadows.—Dr. C. H. Toussaint raised the administrative importance of the two factors, natural healing and active intervention. Public cost had a bearing on it. A waiting-list meant the loss of important early weeks in treatment.—Dr. G. Jessel spoke of the importance of relapses complicating the natural process of healing. He had noticed that cervical glands, after apparent healing with artificial sunlight treatment, might again relapse.—Dr. R. R. Trail said he had obtained help from the sedimentation test in estimating resistance. Apart from pleurisy, which always showed a high rate, chances were good if a patient had a rate of from 9–20 per cent. Over 40 treatment was probably a waste of time.—Dr. F. R. Walters suggested the division of the waiting-list into an urgent and a non-urgent category.—Dr. Basil Price thought that while modern views had swung back to the aerogenous theory of origin, the relation of this theory to lymphatic circulation needed more consideration than it had obtained. In his experience the Ministry of Pensions cases of chronic bronchitis and emphysema, which had been watched ever since the war, not infrequently developed pulmonary tuberculosis.—Dr. S. R. Gloyne was impressed with the different course that the process of healing took in the different natural orders in the animal kingdom. In man the processes of healing were nowadays largely studied by the radiologists, who saw the patient long before the pathologist did, and it was difficult to correlate the morbid anatomy with what was seen on the film.

In the afternoon Dr. L. T. S. Burrell and Dr. N. Tattersall introduced a discussion on the

Future of Artificial Pneumothorax

treatment. Dr. Burrell said that collapse therapy was the simplest method of applying the principle of rest to the lung. All early cases of unilateral disease would, he thought, in the near future be so treated unless there was definite contra-indication; more chronic fibrotic cases by thoracoplasty. One practical objection to collapse therapy was that comparatively few doctors understood it, and a patient might have to travel far for a refill. X ray control was practically outside the scope of the general practitioner. Collapse therapy was occasionally useful in non-tuberculous disease—e.g., to relieve severe pain in pleurisy and in the treatment of abscess of lung.

Dr. Tattersall spoke from the administrative point of view. The first problem was a definite assurance of adequate facilities for the maintenance of refills; the bulk of inductions would probably always be done in institutions. The problem of refills for patients living far from a centre was difficult. He knew of more than one large county borough where the tuberculosis officer did not undertake pneumothorax work, and he had met a sanatorium superintendent who did not believe in the treatment. It seemed to him that the tuberculosis officer must be head of the organisation for doing refills; every year more and more dispensaries were equipped with X rays. A central dispensary was the most suitable place, with special sessions set aside for the purpose. In scattered areas branch dispensaries should be utilised, and the tuberculosis officer would require a portable apparatus. The opportunity for collapse therapy was often lost owing to a patient having to wait. Collapse therapy at home took much time and placed more responsibility on the officer. Arrangements might be made with local hospitals to admit cases for a week or two while the tuberculosis officer did the preliminary induction.

DISCUSSION.

Dr. L. J. Blandford emphasised the difficulty of defining the early case.—Dr. G. Marshall considered the presence of cavity a strong indication for collapse therapy.—Dr. Peter Edwards emphasised the importance of artificial pneumothorax in bilateral cases.—Prof. S. Lyle Cummins mentioned the risk of shutting off the drainage opening from a cavity by collapse therapy.—Dr. J. Crocket remarked that the interval between refills should not be too long. Bilateral pneumothorax was justifiable in advanced cases to make the patient more comfortable.—Dr. Niven Robertson emphasised the danger of compression of the bronchus, and the consequent holding up of pus. He had been impressed with the risk of spontaneous pneumothorax.—Dr. T. R. Elliott suggested the use of the municipal hospitals as pneumothorax centres.—Dr. Edwards spoke of the value of pneumothorax in shortening the course of treatment. Phrenic avulsion immediately after induction enabled the physician to lengthen the intervals between the refills. He had found a small injection of gomenol useful in making the mediastinum more rigid. Screening as a test of movement or hernia of the diaphragm was, he thought, much more important than taking films. Accidents would happen from time to time—in his sanatorium they did about 50 refills a week, and had an accident about once in two years—dispensaries which undertook refills should have an emergency bed available.—Dr. M. Gilbert believed that phrenic avulsion shortened pneumothorax treatment, and was important where a patient could not get refills.—Dr. J. Watt raised the question of ultimate pneumothorax results. He had found it difficult to know what happened to patients long after leaving sanatoria.—Dr. Trail thought the ultimate results were hopeful. The majority of Midhurst patients remained free from symptoms and from sputum, and the treatment was definitely worth while.

On Saturday there was a discussion on Gelatinothorax, reported in our last issue (p. 758).

MEDICAL WOMEN'S FEDERATION.

At a meeting of the London Association of this Federation on March 24th, Dr. Letitia Fairfield, the President, took the chair, and a paper on

Bullous Dermatoses

was read by Dr. Elizabeth Hunt. Symptoms were so obtrusive in skin diseases, she said, that it was not surprising that the obvious lesions had been made the basis of classification, but the result was that nomenclature in dermatology was heavily overloaded. The bulla differed from the vesicle only in size, and both were signs of increased permeability of the vessel walls—a part of the defence mechanism of the skin. Whereas vesicles and bullæ were all produced by the release of a histamine-like substance, bullæ seemed to arise usually when the inflammatory reaction was intense, but sometimes they appeared on normal skin. The contained fluid was first clear but became cloudy or even hæmorrhagic. It contained albumin, fibrin strands, and cells in which eosinophils might predominate. It broke down and left a raw surface, but healing usually followed without scarring. The name pemphigus was now restricted to acute, chronic (or true), and foliaceous pemphigus and pemphigus vegetans. Acute pemphigus was very rare; there was always a history of a wound followed a few weeks later by an outbreak of bullæ with high fever. The condition was fatal and no organism had been isolated. In chronic pemphigus the bullæ appeared in crops without any inflammatory areola and their fluid was sterile. They often appeared first in the mouth or conjunctiva. There was a sensation of tightness and burning, with malaise and irregular pyrexia, but no pain save for that of conjunctivitis. Depression and insomnia followed and the patient was liable to intercurrent disease. The treatment was empirical: to maintain the strength and mitigate the misery. Septic foci should be eliminated. Arsenic was the favourite drug, but in Dr. Hunt's cases quinine had proved better. A water bed and a skilled nurse were essential. The denuded areas exposed by coalescence of the bullæ must be protected. Pemphigus foliaceus was very rare and usually occurred in young women as a persistent eruption of flaccid bullæ, which rapidly ruptured, causing a generalised exfoliative dermatitis which healed slowly. The prognosis was very grave. The diagnosis of pemphigus depended on the bullous eruption, especially in the mouth and eye. In many other conditions bullæ developed later, but were then mixed with other types of lesion.

ALLERGIC STATES.

Dr. Hunt described modern work on allergy and went on to give an account of some allergic manifestations in which cutaneous reactions occurred. Bullæ might cap the wheals of urticaria, of which the commonest cause was sensitisation to a food, though psychical factors also played a part. The treatment was to find the cause, and sometimes an injection of the patient's own proteose would succeed when all else failed. Sometimes a change of environment alone would cure the urticaria papulosa or lichen urticatus of infants, but attention to diet and small doses of grey powder were also valuable. Dermatitis herpetiformis was characterised by polymorphous lesions grouped like herpes and liable to recur. There was a marked eosinophilia but the general health remained good. Herpes gestationis or hydroa gravidarum occurred after the tenth week of pregnancy and might recur in a subsequent pregnancy. It was characterised by multiform lesions with much itching and was extremely hard to treat. Arsenic, bromide, autohæmotherapy, ultra-violet light baths, and proteose injections might be useful. It was believed to be a toxæmia of pregnancy. Cheiropompholyx caused grouped vesicles and bullæ on the palms and soles. It affected women much more than men and was apt to recur, sometimes seasonally. It had to be distinguished from eczematoid ringworm in which a fungus was found.

All these conditions had certain features in common: subjective symptoms, particularly itching, and a psychical factor in the ætiology. In some complex manner the vegetative nervous system seemed to be involved.

There were two bullous conditions of infected origin. The bullous syphilide of infants might be present at birth or appear any time after, but usually about the third week. Prognosis was bad and the treatment was mercurial. It was doubtful whether erythema multiforme belonged here as it might be produced by drugs. It was characterised by symmetrical rose-red lesions of different sizes and shapes with much exudation. There was usually a rheumatic history, and the streptococcus could often be found in the tonsils. The condition had been regarded as a streptococcide and often cleared up with rest, dieting, and salicylates. Bullous erythema multiforme was distinguished from dermatitis herpetiformis by the burning rather than itching sensation it caused. Erythema iris showed a central bulla with a target-like arrangement of concentric rings round it. Impetigo contagiosa was an inoculation of the skin by *Streptococcus pyogenes* and must be diagnosed from the bullous syphilide and epidermolysis hereditaria bullosa which was a congenital vulnerability of the skin in which bullæ were produced by blows and pressure. Finally there were bullous eruptions produced artificially, usually by young women, sometimes obviously to gain sympathy, but sometimes the patients were quite callous. The palatal and conjunctival reflexes were absent in these cases and areas of hyperæsthesia and analgesia could be found.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

A meeting of this section was held on March 13th with Dr. H. F. Moore, the President, in the chair.

Asthma due to Protein Sensitiveness.

Dr. C. J. Murphy showed a woman, aged 30, who was for a long time, he said, almost completely disabled by status asthmaticus. Skin tests showed that she was sensitive to the protein of dog dandruff and removal of her pet dogs stopped the asthmatic attacks. Dr. Murphy demonstrated the patient's skin reaction to the specific offending protein, and showed also that urticaria was provoked by rubbing her arm along a dog's coat.

Dr. E. T. Freeman said that for some years he had been carrying out skin tests in cases of asthma and of urticaria. He sometimes got good results, but at other times complete failure. He had come to the conclusion that in routine practice it was not worth while to do these tests, which were very laborious. They were better in cases of urticaria than in asthma or hay-fever. Sometimes the patient reacted to a substance with which he had never been in contact.

Dr. T. G. Moorhead said that in status asthmaticus he had found Hurst's method of almost continuous adrenalin administration of great service. As soon as the spasms ceased, the adrenalin should, of course, be discontinued.

Dr. Dorothy S. Price said that at Great Ormond-street Hospital, London, deficiency of gastric hydrochloric acid had been found in a large proportion of asthmatic children.

Dr. R. W. Shaw said that in one very troublesome case, not of asthma but of supersensitiveness to some foreign protein, in which the patient during attacks suffered from crops of herpes round the mouth and bullæ on the hands and feet, he had given a series of intramuscular injections of the patient's own blood, and the result had been extremely satisfactory.

Dr. John Mowbray said he had great faith in intravenous peptone injections, both in asthma and migraine.

Dr. Murphy, in his reply, said he had never got satisfactory results from peptone injections. He had had no experience of whole blood injections. He had had fairly good results from the use of ephedrine and of evatmine.

Œdema and Nephrosis.

Dr. A. G. Thompson reported four cases of nephrosis. This syndrome, he said, consisted clinically in œdema and oliguria, without any necessary defect of renal function; biochemically its main features were albuminuria, no evidence of nitrogen retention, a high blood cholesterol, and diminution of the serum proteins, which affected the albumin fraction more than the globulin fraction, so that the albumin-globulin ratio fell. One of his cases was fatal, and the kidneys showed a pure, or almost pure, tubular degeneration. The picture presented by nephrosis was pretty definite, but the cause was far less certain. Possibly it might be external to the kidney—for example, a primary change in the blood proteins. Nephrosis might occur by itself or might be a part of a glomerulonephritis, acute or chronic.

The President said that he had recently had several cases of nephrosis under observation, and in none of them had there been any hypertension. This was curious, for it had been shown that there was usually some involvement of the glomeruli. The appearance of a few red blood cells in the urine did not negative a diagnosis of nephrosis. It was well known that a few red blood cells might appear in the urine of a healthy person. He believed that van Slyke's "urea clearance" test was the best test of the functional capacity of the kidney. He had recently used a modification of that test with excellent results.

Dr. T. W. Dillon asked if Dr. Thompson had estimated the chloride in the plasma and also that in the œdema fluid, and, if so, what was the balance between those fluids. He said that the modern view was that disease was an affection of the whole body, appearing more markedly in one organ than in another.

Dr. Moorhead said he had long since discontinued the use of chlorine-free diets, because he knew of no evidence of chlorine retention in the blood. The retention of chlorides in the body was probably secondary to the retention of œdema fluid in the tissues.

Dr. A. R. PARSONS asked if nephrosis was merely a new term for the condition which had formerly been called chronic parenchymatous nephritis. The possible involvement of the glomeruli seemed to make it very difficult to differentiate nephrosis from glomerular nephritis.

Dr. FREEMAN referred to a case recently under his care which had benefited greatly by treatment by novasurol, and said that novasurol and salyrgan were especially useful in cases of nephrosis. He regarded the presence of blood in the urine as distinctly against the diagnosis of nephrosis. Widal had recognised that chlorides were not increased in the blood even where there was practically no chloride excretion by the kidney.

Dr. MOWBRAY felt that the term nephrosis only made the existing confusion worse than ever.

Dr. R. A. Q. O'MEARA thought that the confusion was due to insufficient consideration of the ætiology. Acute nephritis could be produced either by bacterial toxins and chemical poisons or by toxic proteins produced within the body. Some of the abnormal conditions of the kidney in pregnancy were of the last-named class. The condition of the patient depended on the degree to which the different elements of the kidney were attacked. In nephrosis much protein was lost by the kidney. As a result, the fat reserves of the body were called upon. Imperfect metabolism of fat resulted in the production of cholesterol in excess, and finally the kidney tried to excrete this cholesterol.

REVIEWS AND NOTICES OF BOOKS

A Short History of Biology.

By CHARLES SINGER, Litt.D. Oxford: Clarendon Press, Humphrey Milford. 1931. Pp. 572. 18*s*.

THIS is a readable volume in which the history of biology is set out as a series of problems partially solved, to describe the origin and development of the problems being the objective of the book. It is intended as a fundamental introduction to the study of living things, and an avoidance of technical terms, where possible, corresponds with the wish to make appeal to general readers. In the first 100 pages of the book we have a review of the doctrines and accomplishments of ancient science as represented especially by Hippocrates and Aristotle. The decline and fall of this learning marks the commencement of the Dark Ages, the suggested date being A.D. 200, or just after Galen. A thousand years later comes the thirteenth century revival of learning and the rebirth of scientific inquiry, and this section of the book concludes with an explanation of what Vesalius and Harvey did. In the next section we have set out the historical foundations of modern biology, the influence of the microscope, and the introduction of modern systems of classification; the distribution of life on sea and land is now studied intensively, and the lessons to be learnt from geology bring us to the story of evolution. The third and final part of the book traces the origin of the main themes of contemporary biology from this varied lineage, treats of the emergence of the cell doctrine, the chemistry of protoplasm, the localisation of nervous functions, fermentation and the microbic origin of infectious disease, and winds up with a description of modern work on sex and the mechanism of heredity.

The book is well written and excellently illustrated, and the author is to be congratulated upon having selected for notice from an immense mass of material the things necessary to make a coherent story.

Stepping Stones to Surgery.

By L. BATHE RAWLING, M.B., B.Ch. Cantab., F.R.C.S., Surgeon to St. Bartholomew's Hospital. London: H. K. Lewis and Co., Ltd. 1930. Pp. 228. 12*s*. 6*d*.

THIS book, which is intended to bridge the gap which exists between anatomy and surgery, is essentially a book on anatomy applied to surgical problems, and it is built up on a system which makes it very smooth and pleasant to read. A hypothetical case of some common surgical ailment is described at the beginning of each chapter. The reader is then shown how some of the prominent features of the condition depend upon the original or altered anatomy, and how the problems of restitution to normal may be best carried out from an anatomical standpoint. This is done in an easy armchair style, which is very attractive. Such a work cannot be inclusive, but the student is likely to gain more from this book than from many a complete systematic treatise on applied anatomy because his interest will be retained. Numerous illustrations are provided which, though not of high artistic merit, explain very clearly the meaning of the text and enhance the value of the book.

Chill, its Dangers and Prevention.

By MARIAN THORNETT, F.R.C.S.I. London: J. and A. Churchill. 1931. Pp. 194. 3*s*. 6*d*.

IN a foreword to this book, Dr. Jane Walker points out that a cool, dry skin is able to keep the body at an unvarying, comfortable temperature, and claims that by interfering with this physiological equilibration the use of woollen garments for children "has been fraught with ultimate evil for countless millions of people." The subject matter of the book is an elaboration of this theme, the chapters dealing with such subjects as the standard of national health, the action of chill in lowering vitality, the production of body heat, the skin and its care, clothing in general and clothing for children, baths and exercises, relationship between altitude and chill, diseases often produced by chill, psychology of the fear of cold, and "hardening."

Dr. Thornett's iconoclastic attack on our civilisation is not confined to our methods of clothing ourselves and our young, and, indeed, it is obvious that our ways of living must be revolutionised if the skin is to exercise its functions to their full extent. Some of the evidence here adduced, however, is scarcely adequate to support her contentions. The Army and Navy recruiting figures for 1913 and recent years would require much closer scrutiny before they would justify the conclusion that our physique is deteriorating, and surely everyone is aware of the fallacies to be avoided in interpreting the Health Insurance records of recent years. That "a cold is always the result of chill," and "at least one-third, and in all probability more than that, of the illnesses which end fatally are preceded by chill, while perhaps 50 per cent. of the illnesses from which we recover are due to the same cause, directly or indirectly," are statements which, we think, are not substantiated by any accurately ascertained facts. While this book shows evidence of much thought and great enthusiasm, it would have been more convincing if less bias had been shown in the analysis of some of the data put forward. Nevertheless, while it is hardly correct to say that "the effect of clothing on the body has never been investigated," Dr. Thornett's book will have done good if it leads to a greater interest in the subject and to a scientific inquiry into it.

Among the Thinkers: Leaves from My Note-books.

BY J. A. LINDSAY, M.A., M.D., F.R.C.P. London: H. K. Lewis and Co., Ltd. 1931. Pp. 198. 5*s.*

PROF. Lindsay's little book of quotations makes a generous well of worldly wisdom into which one may dip anywhere and bring up a well-turned phrase, an acute observation, or a profound reflection. Inevitably one skims such an anthology seeking a revelation of the character and personality of the collector. The impression is of a man, sane, kindly, dignified, tolerant, English rather than the acrid Scottish flavour to be expected from the author's patronymic. The quotations from Anatole France give a welcome spurt of ironic colour and suggest that another facet of Dr. Lindsay's mind would modify this impression.

Introduction to Medical Biometry and Statistics.

Second edition. By RAYMOND PEARL, Professor of Biology, School of Hygiene, Johns Hopkins University. London: W. B. Saunders Co., Ltd. 1930. Pp. 459. 25*s.*

NOT many text-books on statistics have been specifically written for the benefit of the medical man. Many of us can recall our own introduction to the subject in the short, sometimes unintelligible and even inaccurate remarks on birth- and death-rates, standardisation, estimation of intercensal populations, and perhaps on life tables, which are commonly relegated to the concluding pages of manuals of hygiene and public health. The medical man with slight mathematical equipment has found somewhat indigestible the fare provided in general and special text-books of statistical theory and method, and in the past has shown little enthusiasm for this branch of knowledge. An elementary knowledge of statistics is, however, almost essential to those who wish to draw valid conclusions from the clinical material they have collected. Prof. Pearl is prepared to pilot the tyro through some of the initial difficulties, and in so doing illustrates the applicability to everyday problems of the more common and useful biometric methods.

In the second edition his book has been largely rewritten and enlarged; perhaps the most important additions are the more detailed consideration given to the methods of collecting, and the essential ideals in making scientific records, and the chapter dealing with the logistic curve. Beginning with historical and introductory matter, the author deals in logical sequence with the collection of the basic data, their tabulation, presentation, and methods of analysis. The field covered includes all that is required for the successful handling of medical investigation—rates, ratios, life tables, averages, measurement of variation and correlation, simple curve fitting, elementary theory of probability, and that mysterious appendage to statistical constants, the probable error. The mathematical details supplied are few, and they are, moreover, presented in a manner intelligible to any medical reader. The bibliography appended to each chapter is carefully chosen and sufficiently extensive, and the discussion of methods is frequently interspersed with allusions to current medical and biological problems.

The new edition can be recommended to physicians who feel the need of guidance in the compilation and analysis of their records, and we trust that more and more of them are becoming conscious of this need.

Der Appendicitische Anfall.

By LUDWIG ASCHOFF. Berlin: Julius Springer. 1930. Pp. 125. R.M.12.40.

THIS monograph embodies those researches of Ludwig Aschoff which were designed to elucidate the problem of the infecting organism in acute appendicitis. Amongst the host of bacterial strains found in the alimentary canal in such cases it is difficult to determine which shall be counted amongst those of ætiological significance. Phagocytosis in an early stage is accepted by the author as the criterion of pathogenicity, and this book is an account of the problem from this standpoint. It is short, easy to read, and has definite value as a contribution to the subject.

Practical Anæsthetics.

For the Student and General Practitioner. Second edition. By C. F. HADFIELD, M.D. London: Baillière, Tindall and Cox. 1931. Pp. 350. With 41 figures. 7*s.* 6*d.*

THIS excellent handbook has been considerably enlarged since its first appearance, chapters having been added on splanchnic, local regional analgesia, and local analgesia in dental practice. The latest methods and drugs come in for due consideration with the exception of the barbiturates which the author thinks not yet sufficiently well established. Dr. Hadfield has wisely omitted large numbers of anæsthetic machines from his pages since these are mostly apparatus only for the use of specialists, whereas this book is eminently suited to the general practitioner. His general advice is sound and his descriptions of methods and of the principles involved are always clear and logical. We note that he predicts the inclusion of nitrous oxide in the next issue of the British Pharmacopœia with due tests and standard of purity, an addition long overdue. We notice, also, in explanation of massive collapse of the lung, that the author attributes this "to some characteristic spasm of the bronchial musculature . . . associated with some disturbance of the sympathetic innervation." He does not mention inhibited action of the diaphragm to which many authorities attribute the lung condition. Dr. Hadfield gives a good deal of space to percaine which he obviously regards as a very valuable addition to the list of local analgesics, particularly for spinal use. His book went to press, of course, before the recent decease (official) of "status lymphaticus," so that condition now generally regarded as mythical still figures in the book as a source of danger to be borne in mind when chloroform is used on children. The printing of this book adds to the pleasure of reading it.

Diseases of the Urinary Tract in Children.

By EDWIN BEER, M.D., and ABRAHAM HYMAN, M.D. London: William Heinemann Ltd. 1930. Pp. 318. 25*s*.

THIS book contains a series of monographs in which the authors present the experience they have acquired in the past 20 years, mainly in the wards of the Mount Sinai Hospital. One of the most interesting sections is a discussion on the surgical treatment of nephritis. The authors consider that decapsulation is of value in the acute type of this disease, and in the chronic type with acute exacerbations, but less so in the more chronic lesions. It is, perhaps, rather confusing to have included perpetual incontinence due to congenital deformities in the chapter headed "Enuresis"; and the section on the treatment of vesical calculi is not convincing. The number of young male children in whom litholapaxy is possible must be small. As a whole the book is interesting and instructive. Illustrative cases and a bibliography are appended to most of the sections, and there are some good illustrations.

Life Movements in Plants.

Edited by Sir JAGADIS CHUNDER BOSE, D.Sc., F.R.S. London: Longmans, Green and Co., Ltd. 1931. Pp. 211. With 80 text figures. 18*s*.

THIS is the sixth volume of the Transactions of the Bose Research Institute in Calcutta, and contains a number of contributions to the physiology of plants by the Director and his pupils. They deal mostly with rhythmic movements, the transmission of stimuli from one part of a plant to another, and the ascent of sap and, as before, are characterised by great refinements in methods of automatic recording and by the idea that the working of plants finds many close analogies in animal mechanisms. Three papers concern the proteolytic enzymes of plants, and it is interesting to note that the results which Prof. S. H. Vines reached 25 years ago are maintained against recent efforts to impugn their accuracy.

Text-book of Inorganic Pharmaceutical Chemistry.

For Students of Pharmacy and Pharmacists. By CHARLES H. ROGERS, D.Sc. (Pharm.), Professor of Pharmaceutical Chemistry in the College of Pharmacy, University of Minnesota. Philadelphia: Lea and Febiger. 1930. Pp. 676. $7.00.

To those in search of historical information or particulars of natural sources, explanations of qualitative or quantitative methods of the pharmacological action of ions, and therapeutic uses of drugs, this book may prove valuable as a reference work. The author states that the elements have been considered in the order in which they occur in natural groups or families, and then proceeds to ignore this plan by beginning with oxygen, hydrogen, nitrogen, taken from Groups 1, 6, and 5, and then proceeding to the halogen family (Group 7), the alkali metals, the coinage metals (sic), deals with the alkaline earth metals, beryllium and magnesium and their compounds, boron aluminium and the metals of Group 3, Group 4, the phosphorus family, and Group 6, in which he includes manganese which, of course, strictly speaking, belongs to Group 7. In itself there is no harm in the arrangement adopted but it does not actually conform to the opening statement. The book contains quite a quantity of information likely to stimulate interest, but it is marred by a certain lack of discrimination; this is illustrated by the tendency to represent by equations reactions which do not merit such treatment, as, for example, the decomposition of sodium acetate on ignition; incidentally the equations (2), (3), and (4) on page 229 do not balance. The book shows other signs of needing revision; on page 27 occurs the statement that the pH drops to neutrality when actually it is the acidity which drops while the pH rises; on page 598, line 17, ferric oxychloride should read ferric chloride. As an example of loose method of expression we may quote the first sentence of the preface in which the term qualitative chemistry is apparently used to imply qualitative analysis. In spite of these faults the book will give useful information about the properties and mode of action of many inorganic substances used in pharmacy to readers who have sufficient knowledge of chemistry to be able to read it with discernment.

Nutrition and Food Chemistry.

By BARNARD S. BRONSON, State College for Teachers, Albany, N.Y. London: Chapman and Hall. 1930. Pp. 467. 18*s*. 6*d*.

ALTHOUGH no inconsiderable part of this manual is directly concerned with the chemistry of foods and foodstuffs, the arrangement of the material is so well planned and its exposition is so clear that scarcely any previous knowledge of chemistry is necessary to enable the argument to be followed. The first part of the book deals with the chemical structure, the intermediary metabolism, and the physiological properties of the constituents of foods, and includes an account of the food and energy requirements of the normal human being. The second part is occupied by a discussion of the nutritive properties of individual common foods, and deals with methods for their production and preservation. Numerous references to recently published work would enable the reader to examine the evidence upon which the conclusions are based. This volume can be recommended strongly to those who wish to understand the fundamental principles underlying the science of nutrition.

A Text-book of Practical Therapeutics.

Twenty-first edition. By HOBART AMORY HARE, B.Sc., M.D., LL.D. Professor of Therapeutics, Materia Medica, and Diagnosis in the Jefferson Medical College of Philadelphia. London: Henry Kimpton. 1930. Pp. 1104. 36*s*.

IN its twenty-first edition this work has been enlarged, thoroughly revised, and largely rewritten, but there is no alteration in its general plan and arrangement. It deals first with general therapeutical considerations, then with the pharmacological action and therapeutical uses of drugs and other remedial agents, and finally discusses the treatment of individual diseases, arranged, not in systems, but in alphabetical order. It contains, in addition, a Therapeutic Index, which should prove a useful means of obtaining quickly suggestive ideas as to treatment. Many of the newer methods of treatment, such as the intravenous use of tartar emetic in the treatment of chancroids, and the employment of irradiated ergosterol in rickets and stomach extracts in pernicious anæmia, are discussed. The author has obviously kept abreast of modern advances in pharmacology and therapeutics, and the book is likely to maintain its deserved popularity.

THE LANCET.

LONDON: SATURDAY, APRIL 11, 1931.

SILICOSIS: INTERNATIONAL RECORDS.

Considerable interest attaches to the account only just published of the proceedings at the International Congress which met in Johannesburg to discuss silicosis in August, 1930.[1] The International Labour Office deserves thanks for organising the congress and for this publication, which must become a standard work of reference. The discussions at each session are reported more or less in detail, and the general conclusions reached as the result of the conference are set forth in the reports of the eleventh and twelfth sittings. These conclusions and recommendations are rather hidden in this position, and, in view of their importance, might have been given prominence at the beginning or end of the volume.

The chief value of the book lies in the series of papers prepared beforehand by various experts for the consideration of the congress, and the value is high. The opening articles deal historically with conditions in the South African gold mines, which led some 30 years ago to the origination of silicosis among the miners, and with the progressive steps taken to combat the disease, which include control of blasting operations to minimise exposure to the dust generated, the use of water-feed drills to prevent the formation of dust during drilling, and improved ventilation to dilute and remove vitiated air. The gold reefs consist of quartz pebbles in a hard siliceous matrix; hence arises silica dust during mining operations. The dust has been determined either gravimetrically by drawing mine air through a column of sugar and then dissolving the sugar in water, from which the dust is filtered and weighed, or by counting the particles caught on a glass microscope slide when air is made to impinge on it. Figures given show a vast improvement in 1929 as compared with the dust in mine air in 1914. Ætiology is well stated; it depends on intensity, duration, and continuity of exposure to phthisis-producing dust; it is favoured by high humidity, which favours infection; infection should be regarded as seriously as in an operating theatre. The sections devoted to pathology, radiology, and symptomatology are particularly useful, and are excellently illustrated; they must for long form the basis of accepted knowledge on the subject. Amid so much that tells of the progressive and fatal nature of silicosis, illustrations of cases, still healthy, 8, 12, and 21 years after being diagnosed as well-marked instances are refreshing. A series of papers tells of the occurrence of silicosis in other countries; in the various States of Australia the disease is mainly concerned with gold mining, just as in South Africa; and in Canada also it has usually taken the form of miners' phthisis, although some granite cutters have been affected. The disease has been more general in Germany, attacking rock drillers, potters, metal grinders, and masons; here recognition has recently been widely given to its importance. The article by Dr. E. L. Middleton describing silicosis in Great Britain is the most thorough of the series, setting out its prevalence in numerous industries, the extension to them of compensation rights, and the adoption of preventive measures; the industries concerned are the refractories, grinding of metals, work on sandstones and granites, slate quarrying and dressing, coal mining, tin mining, pottery, sand blasting, silica milling, flint crushing, millstone dressing, and flint knapping. Interesting facts are also stated with regard to pneumonoconioses in Italy and the Netherlands. The article dealing with the United States, although only a brief summary, displays the disease as widespread, and attracting increasing interest in many industries, while it is also the subject of research work.

This important record closes with explanations of how the Miners' Phthisis Medical Bureau functions at Johannesburg, and of how, by progressive legislation, the disease is being steadily brought under control. As the congress proceeded the importance of the data on all aspects of the silicosis problem which has been accumulated in South Africa became more and more apparent. At the eighth sitting of the conference, on August 20th, Dr. L. G. Irvine, who presided, stated that the figures showed that silicosis was definitely on the decline, especially among new rand miners. Dr. A. J. Orenstein suggested that though the statistics presented by Dr. Irvine and Dr. Spence Fraser were perfectly reliable, they did not reflect the whole picture. It was very difficult to visualise all the factors without biological and engineering knowledge. Prof. A. J. Hall and Prof. E. H. Kettle supported his plea for an even wider and more searching survey of the unique material collected in South Africa from a biometrical basis. So many factors are concerned in the problem that the analysis of the figures is a matter of extreme difficulty. It may be hoped that at least one result of the conference will be an investigation of this kind, since the statistics of South Africa are of the utmost importance to all countries which have to initiate legislation in connexion with silicosis.

MEDICAL BENEVOLENCE.

No man knows with certainty what awaits him in the future, but to one section of the medical profession the future is definitely clouded and dismal. It is this section to which the Royal Medical Benevolent Fund has devoted its attention for the last 95 years. It is probable that in many cases in which relief is sought there has been lack of prudence although, as Dr. C. O. HAWTHORNE remarked at the recent annual meeting of the Fund, the lack is not necessarily on the part of the applicant. In any case, he added, the position is not to be met by the critical examination of the economist or of the moralist but by the generous judgment and help of those who are more fortunate. The Fund offers relief over a wide range of circumstances. It helps one practitioner who, as the result of illness or accident, finds himself unfit for work and in danger of destitution ; it helps another who, by age or misfortune, has been reduced to penury or helplessness ; it helps the widow of the medical man who has been left almost penniless ; it helps the elderly daughters of a deceased practitioner who by age, incapacity, or illness are no longer able to earn a livelihood ; it helps to educate or to find work for the members of a deceased practitioner's family ; and it helps by an immediate grant to solve an acute emergency in a practitioner's fortunes. These aims need no support from us, but it is true now as it always has been that examples of individual misfortune make stronger appeal than the recital of group sufferings. Two cases helped by the Fund during recent months are these :

---

[1] Silicosis. Records of the *International Conference* held at Johannesburg, August 13th–27th, 1930. International Labour Office. Studies and Reports. Series F (Industrial Hygiene), No. 13. Geneva. Pp. 692. 1930.

(1) A doctor, aged 76, has been bedrid for the last two years following a stroke. He is now quite childish and unable to look after himself. His two sisters are entirely dependent on him ; the elder is confined to bed with cancer of the bowels, the other, about 60 years of age, is very frail and alone looks after these two invalids. She cannot afford a servant or nurse to help her, and has to do all the housework and nursing herself. There is only £110 a year for these three to live on. The Fund voted its maximum grant of £40.

(2) A doctor's widow, aged 65, has since the death of her husband been entirely dependent on her eldest daughter for support. The daughter, who was making a success in her profession as an actress, died after a short illness from pulmonary tuberculosis, leaving her mother penniless. Other charities contributed £55. The Fund voted £36.

Apart from cases like these there is on the books of the Fund a long list of widows of medical men who have no other income than the old-age pension of £26 a year. If it were not for grants of £26 from the Fund, or annuities of £36 which are available for some of them, they would have to submit to the ignominy of seeking outdoor relief.

The amount of distress among the members of our profession seems to be still but faintly realised. Last year 661 grants amounting to nearly £10,000 were made in all : 331 of these were maintenance grants, 16 educational grants, 27 assistance in time of illness, 43 were made for specific purposes, 24 emergency grants in temporary difficulties. The total number of annuitants is 177, and largely as a result of the legacy of the late Dr. ALEXANDER LAWRENCE there are five persons receiving pensions each of £100 a year. The total expenditure on grants has been nearly £1000 more than during the previous year owing to an increase in income from the accession of 584 new subscribers, the revenue from subscriptions and donations for the first time reaching five figures. Of these, 223 came through the British Medical Association which collected £1970 for the Fund during the year. A special appeal to medical societies and panel committees yielded a response from 23, bringing the total number supporting the Fund to 86. A donation of £630 was received from the Medical Insurance Agency. Sir THOMAS BARLOW, President of the Fund, described the reports of honorary secretaries and honorary treasurer as eminently satisfactory, noting that the Fund had made definite progress during the year in securing the support of the profession. While no doubt in these hard times any increase in benevolence must be regarded with satisfaction, the position is hardly to be regarded with complacency in which 55,291 registered practitioners raise among themselves the sum of £10,082 in the course of the year. The amount is precisely 3*s.* 7*d.* a head. A subscription from each of one guinea a year would enable the Fund to assist adequately all who apply for help.

The trouble of the Royal Medical Benevolent Fund is the number and variety of the claims made upon it. To some extent the Fund is able to act as a clearing-house for other charities, and there is sound reason why it should not be calle upon when help is available elsewhere. Probably the most distressing kind of case which comes before its officials is that of the young medical man who has died early in his career, before having made provision for his wife and young children. For this particular kind of risk there is in the London area an established and endowed agency known as the Society for Relief of Widows and Orphans of Medical Men. By payment of an annual subscription of two guineas a newly married man gets the satisfaction of knowing that his wife will receive support and his children education in the event of his early death ; such protection would cost him many times as much at a life assurance office. There are many directions in which a young practitioner needs to safeguard himself, and although no doubt some are in a position to cover themselves against all possible risks, there are others who must either unduly postpone marriage or live under a cloud of anxiety in the early years. For such as these, until success in practice enables them to make *provision for* dependants, an annual subscription to the "Widows and Orphans" has a provident character. When success renders the *practitioner's* dependants ineligible for benefits from this society, the subscriptions become of a purely benevolent nature, safeguarding the fund *for others* less fortunate. The society has a long and honourable career o nearly 150 years, and no arrangement would bette meet the domestic anxieties of the young practitioner. Its membership is however limited t those who at the time of application are residen within a radius of 20 miles from Charing Cross though adherence later is not affected by chang of residence. The house officers of all th London hospitals are eligible.

STREPTOCOCCAL INFECTIONS.

THE study of the staphylococcal infections as a group made up the greater part of the *Guy's Hospital Reports* for April, 1930. In the January issue which has lately appeared the streptococcal infections are dealt with in much the same way by nine different observers. Dr. J. A. RYLE, whose paper opens the symposium, believes that although the symptoms of invasion of the blood stream by the streptococcus are varied they can be collectively considered as manifestations of streptococcal fever. Such a presentation is complicated by the large number of strains of streptococcus capable of causing blood poisoning and the many possible routes of invasion. If surgical injuries are excluded, Dr. RYLE thinks that the most apparent causes predisposing to streptococcal fever are other infections and anæmia. Septicæmia may, of course, originate by invasion of a cutaneous or mucous surface or deeper structures, or without an evident local focus. He finds that four manifestations seem to be peculiar to streptococcal fever due to a hæmolytic strain—namely, frequent and troublesome diarrhœa, albuminuria with red cells and casts, rapidly progressive anæmia, and a smooth, red, desquamated and sore tongue. He bases the diagnosis of streptococcal fever of the septicæmic type on the association of high fever, rigors, quick pulse, delirium or an over-alert mentality, rapid splenic enlargement, and metastatic infection of serous cavities. A lobar pneumonia may complicate a streptococcal invasion, and when such a pneumonia is accompanied by anæmia and is slow to resolve Dr. RYLE finds that lung puncture usually gives a hæmolytic streptococcus. The medium or larger joints, the pleural sacs, the pericardium, the meninges, and the peritoneum are the favourite sites for metastatic abscesses, although a streptococcal septicæmia may run its course to death or recovery without metastatic symptoms. As regards prognosis Dr. RYLE believes that those patients who survive the first onslaught and weather the first fortnight have a fair prospect of recovery, even when high pyrexia continues and complications ensue; other points in favour of a good prognosis are a surgically accessible focus of invasion, a high leucocytosis, and metastatic localisations which are amenable to surgical treatment. Unfavourable localisations are those involving the meninges or the pericardium. A careful watch for the development of localised infection, in order that aspiration or drainage may be undertaken early, is an important element in the treatment of these infections; when blood cultures become negative but the temperature remains high, the search for metastases must be pursued with special care. Otherwise the treatment should include good nursing, a copious fluid intake, morphine for pain, and immobilisation of affected joints. There is no sound evidence, Dr. RYLE says, that chemical antiseptics by the intravenous route do good, and the value of antistreptococcal serum is also open to debate. To be given its best chance the serum therapy must be begun early, within the first 48 hours, and in adequate dosage; it should not be continued blindly if no improvement follows the first few doses. It is perhaps unfortunate that Dr. RYLE does not make clear, in the 21 case-histories which he quotes, on which day of illness blood cultures were taken. The diagnosis of septicæmia presents many difficulties, and is often only clinched by the discovery of bacteria in the blood; it would be useful to know at which point in the cases quoted this confirmation became available. Apparently, a positive blood culture cannot be obtained early enough to determine the use of serum if this is to be given during the first 48 hours; serum therapy should therefore be undertaken on the strength of a diagnosis based on symptoms.

Writing on streptococcal puerperal sepsis Mr. G. F. GIBBERD quotes the work of COLEBROOK, BURT-WHITE, and others who have found that among non-fatal cases infection by a hæmolytic streptococcus alone occurs in only 8 to 30 per cent. of cases. Of the fatal cases the majority are due to *S. pyogenes*, but *S. viridans* and non-hæmolytic streptococci and a group of anaerobic streptococci may also be responsible in a few cases, Mr. GIBBERD considers. Since the vulval skin cannot be excluded as a source of infection, he believes that the use of antiseptic lotions still has a place in midwifery and should not be discarded as valueless. He urges the importance of wearing a mask when attending a confinement, a simple precaution which has been generally neglected. Recent investigations show that the throat of the attendant has sometimes been the source of the streptococci which killed the patient. Since fatigue and acute anæmia play a part in the incidence of sepsis, Mr. GIBBERD advises blood transfusion in all cases of severe hæmorrhage, preferably before the patient shows signs of infection. The method, introduced by REMINGTON HOBBS, of instillation of glycerin to promote drainage of the uterus, has suffered, in Mr. GIBBERD'S view, from too little insistence on the technique to be employed; glycerin introduced with bad technique may do more harm than good. He recommends anti-scarlatinal serum early in the disease, but deprecates the pious hope of a blunderbuss action which inspires the injection of antistreptococcal serum.

Mr. T. B. LAYTON is able to state that there is no particular clinical type of acute mastoiditis due to the hæmolytic streptococcus. He believes that useful information would be obtained by the routine culture of bone from cases of acute mastoiditis. In chronic mastoid disease he points out that it would be valuable to know at what point the primary organism, usually a hæmolytic streptococcus, is killed off and the bone becomes sterile, and the subsequent point at which secondary infection of the abscess develops. A paper on streptococcal diseases of the skin is contributed to the symposium by Dr. H. W. BARBER; and Dr. L. FORMAN writes on the value of intradermal tests with *S. hæmolyticus*, *S. viridans*, and staphylococcal vaccines in cases of erythema multiforme and lupus erythematosus. Successful treatment by intradermal vaccination has been recorded in two cases of erythema multiforme. Dr. F. A. **Knott** gives a survey of the streptococcal types and their significance in clinical medicine, and acute streptococcal infections of the throat are discussed by Mr. W. M. **Mollison**. Dr. **Arthur Bulleid** contributes a bacteriological study of the apical infection of teeth, and a remarkable case of streptococcal septicæmia with peritoneal localisation is described by Mr. **Philip Turner**.

ANNOTATIONS

THE TRAFFIC IN DANGEROUS DRUGS.

Reports of the fourteenth session of the advisory committee on the traffic in opium and of the seventh session of the Permanent Central Opium Board are full of interesting, but not very reassuring, information about the licit and illicit commerce in "dangerous drugs." There are still many States which have not yet ratified the Geneva Convention of 1925, including four which are members of the Council of the League. The illicit traffic in 1926–29 was on an even more considerable scale than was suspected. Apparently some 21 tons of morphine and heroin were exported to non-manufacturing countries in excess of medical needs, and about 15 additional tons of these drugs, statistically unaccounted for, passed into illicit traffic in the five years under review. Moreover, six tons of benzoyl-morphine, hitherto an unscheduled drug, passed in 1928 through the single port of Dairen, an amount which represents 600,000,000 doses. Large seizures have been made of cocaine smuggled into India, mostly of Japanese origin, while considerable quantities of contraband Persian opium find their way into China. It is lamented that four out of the six chief opium-producing countries—viz., Turkey, Persia, Russia, and China—are at present outside the Geneva Convention, and attention is drawn to the fact that States which are parties to the Geneva or the Hague Conventions have failed to follow up the ratifications by legislation on the lines of the Dangerous Drugs Acts 1920–25 of Great Britain.

If we turn to the report of the Permanent Central Opium Board, which deals with the statistics for 1929, we learn that the returns received from several countries are incomplete; this is so even in the case of France, while from southern and central America there is an almost entire lack of information. As Peru and Bolivia are among the chief producers of coca leaves such absence of information is regrettable. Owing to the conversion of morphine into substances not covered by the Conventions it is inferred that in 1929 12 tons of morphine were manufactured in excess of that required for legitimate purposes throughout the world. There are strange discrepancies in regard to the consumption of cocaine and heroin in different countries. Thus the Australian consumption of cocaine is double that of other Anglo-Saxon countries, and, while in France the consumption of heroin is at the rate of 21·6 kg. per million inhabitants, in Anglo-Saxon countries it is only 2·21 kg. The Board is led to the conclusion that drugs are escaping from licit into illicit traffic, but finds that under the Geneva Convention it is unable to obtain such information as to the contraband commerce as will enable it to act with promptitude and efficiency. Moreover, the tables supplied for raw opium show no sort of agreement as to imports and exports. Much is hoped from the new conference on the limitation of traffic in dangerous drugs to be held next month in Geneva. It is somewhat astonishing to learn however from an answer recently given in the House of Commons that "the question of limiting the production of raw opium is outside the scope of the conference." It will be remembered that it was a similar exclusion from consideration of the production of the raw materials of dangerous drugs that was largely responsible for the withdrawal of the American delegation, followed by that of the Chinese, from the Geneva Conference of 1924–25. It will be, to say the least, anomalous if such exclusion is again persisted in.

ALLEVIATION OF PAIN IN CHILDBIRTH.

If ever there is a serious endeavour to supply anæsthesia during labour for all women who desire it, the main problem in England will be how to arrange for the 60 per cent. of confinements that are conducted by midwives. There can never, we imagine, be any question of putting the administration of true anæsthetics into the hands of these women, unless their training develops into something far in advance of its present state. It is possible, however, that some form of sedative might be contrived which could be prescribed by the doctor and administered by the midwife, and which might be an effectual means of diminishing or abolishing the pains of labour without interfering with its progress. A possibility of this kind is forcibly brought to mind by the practice described by Prof. H. Sellheim,[1] who discusses the difference between twilight sleep and pain alleviation. He recommends a mixture composed of half the maximum dose of omnopon, and half the maximum dose of scopolamine, given in brandy and syrup by the mouth about half an hour before the birth of the head is expected. This administration can, he says, be safely entrusted to the midwife, and is effective in relieving the worst pains of labour. Obviously there may be a great deal of pain endured before the correct time arrives for the dose, but this practice looks to us like a definite step in the right direction.

RELAPSES IN SCARLET FEVER.

Dr. A. Lichtenstein,[2] director of the Epidemic Hospital at Stockholm, defines a relapse in scarlet fever—which was first described by Körner in 1875—as the reappearance during the course of the disease of its principal symptoms, especially the eruption, in which it is possible to produce a Schultz-Charlton extinction reaction with convalescent serum or scarlatinal antitoxin. The frequency of relapses varies according to different observers, but usually ranges within the narrow limits of 0·5 and 1·0 per cent. Up to 1925 the percentage of relapses in scarlet fever at the Stockholm hospital was 0·5 to 0·6 annually. Since that date, however, there has been a striking increase in their frequency, amounting to as much as 10 per cent. in 1929. Lichtenstein is inclined to attribute this increase to the remarkable mildness of the disease in recent years, which results in the immunity produced by the attack being less complete than usual. Unlike A. H. G. Burton and A. R. Balmain,[3] he found that cases treated with scarlet fever antitoxin showed a lower proportion of relapses than those not so treated; of 578 cases treated with antitoxin between 1926 and 1929, only 6·2 per cent. developed relapses, as compared with 9·3 per cent. among 1462 controls. The same was true to a still greater extent of cases treated with convalescent serum. Between 1916 and 1929, 761 scarlet fever patients were given convalescent serum, and only 0·8 per cent. had relapses, as compared with 12,860 controls during the same period, of whom 1·7 per cent. relapsed. In Lichtenstein's experience children between the ages of 5 and 10 years were more likely to develop relapses than adults. The relapse, he says, may appear at any stage of the disease, but is commonest in the third or fourth weeks. As a rule it is mild in character, but occasionally it is severe, and in four cases observed at the Stockholm hospital it ended fatally. As regards the cause of the relapse the question whether it is endogenous, as Lichtenstein maintains, or exogenous, is still unsettled. G. Fanconi, who supports the theory of exogenous reinfection, states that the problem can only be solved by comparing the course of scarlet fever in patients treated in separate rooms and in large wards. No such investigation, however, has yet been made. In a recent communication Burton and Balmain,[4] who as already stated found that antitoxin treatment increased the frequency of relapses, maintain that this tendency to relapses can be prevented by Dick-testing the convalescents and separating the positive reactors from the other patients—clear convalescent patients being removed to a convalescent ward from which they are discharged three weeks after admission to hospital, while patients with nasal, aural, or purulent discharge should be treated by the barrier or bed-isolation method—and lastly by keeping patients in the open air as far as possible.

STERILITY OF CATGUT.

NEARLY all surgeons will agree that on the whole catgut is the best substance of which to make ligatures and buried sutures. It is true that catgut ligatures are liable to slip occasionally, but care will guard against this happening. Their most valuable quality is that they can be wholly absorbed, and thus the permanent presence of a foreign body is obviated. They have, however, one great disadvantage—namely, that in the crude state catgut is the seat of a large number of micro-organisms, and certain difficulties are encountered in the endeavour to remove these completely. From its chemical constitution catgut cannot be boiled; the temperature necessary for sterilisation in this way will destroy the material itself. Other methods, therefore, are constantly being devised, and in our issue of Feb. 14th, for instance, Mr. Arthur Porritt described one which has been successfully employed at St. Mary's Hospital for the last nine years. It consists essentially in the employment of oil of peppermint, as suggested by Captain S. R. Douglas, F.R.S., and the process apparently makes the catgut absolutely sterile without diminishing its tensile strength. Absorption proceeds rapidly with very little reaction or fibrous tissue formation. Another interesting paper on the subject is contributed to the February number of *Surgery, Gynecology, and Obstetrics* by F. L. Meleney and Mabel Chatfield, of New York. They began by studying 174 specimens of "prepared catgut" obtained from 12 surgical clinics or purchased in the open market. The specimens were labelled with the names of 17 different manufacturers or distributors, except eight which bore no labels, and all of them were sealed in glass tubes. Each of the samples was tested for the presence of micro-organisms. Those from ten firms yielded no growth on culture media, but the products of seven firms, and all the unlabelled tubes, showed growths in from 5 to 67 per cent. of the specimens tested. In every instance the germs present were spore-formers only, and no pyogenic cocci were found. The second object of the research being to evolve a standard test of sterility, an attempt was made to produce a culture medium in which anaerobic spore-forming bacilli will grow readily. The medium should be a clear fluid with adequate nutrient substances, and it was found that the most suitable was a meat infusion with peptone and reducing substances such as glucose and gelatin. The tube should be closed with an impermeable material such as vaseline, and before being placed in the medium the catgut should be washed as free as possible from the bactericidal fluid with which it has been sterilised, neutralisation being required if chemicals have been employed in sterilisation. Before the batch is liberated for sale the tubes must be incubated for at least 15 days without any evidence of growth.

MOSQUITO CONTROL IN ENGLAND.

THE risk to life and health from mosquitoes in England is, comparatively speaking, negligible, but as a source of discomfort, as well as of economic loss, they call for close consideration. Although the problem is not fundamentally medical, the latest report of the director of the British Mosquito Control Institute contains much that will interest practitioners and sanitarians as well as entomologists. About a decade ago, when parts of Hayling Island were by all accounts almost uninhabitable owing to the mosquito nuisance, a resident there took up the study of mosquito control as a hobby. At first the work done was mainly or entirely local, but it proved too valuable to remain so, and in 1925 the British Mosquito Control Institute was formed and the present building was erected and equipped. It is the only existing institution entirely devoted to research of this kind. The present report covers nearly two and a half years, and the work is described under three headings—advisory, research, and educational. The first consists in supplying advice by visits of inspection and by correspondence, a prearranged charge including a report on the species of mosquitoes found, and the remedial measures recommended. In one well-known golfing resort a serious mosquito nuisance has been ended by a local scheme on lines suggested by and under the periodical supervision of the Institute. In connexion with this aspect of the work a small illustrated pamphlet ("How to Recognise and Collect Mosquitoes and their Larvæ") has been prepared for inquirers. The research also is described under three heads: first, routine examination of specimens collected by the staff or sent to the laboratory (this might more appropriately come under the heading of advisory work); secondly, many kinds of investigation either arising from laboratory routine or undertaken by request (e.g., testing of larvicides); and thirdly, specified pieces of investigation carried out by science teachers, university students, and others using the Institute equipment and the services of its staff. The instructional work has included that done in connexion with a malaria course for medical officers arranged by the London School of Hygiene and Tropical Medicine, elementary or advanced short courses on mosquito control or research, and casual information given by the staff to visitors to the museum, who have numbered 6551 in the past five and a half years. Photographs and lantern slides are also produced and lectures and demonstrations are given at scientific meetings. No detailed account of the work is attempted in the report, but certain items of interest are described. Among these may be mentioned the investigation of a number of females of *Aëdes cinereus* from the neighbourhood of Birmingham which were infested with larval hydrachnid mites, and a study of the habits of *Culex pipiens* by a zoology student of Cambridge University. An account is given of modifications and developments in the special apparatus originally designed by the Director in 1923 for ordinary and stereoscopic photography of insects, and a chart is reproduced which gives particulars of larvæ collected on Hayling Island.

COST OF MEDICAL EDUCATION IN AMERICA.

It is generally reckoned in this country that it costs round about £1000 to obtain a medical degree, without, of course, counting the money that the student might be earning during his five or six years' education. The figure naturally varies with the amount of hardship which he is prepared to endure and with the fees and extras of the particular college which he selects. It is interesting to compare this rough popular estimate with a careful investigation of the costs of medical education in the United States which was published recently by Dr. R. G. Leland.[1] He finds that the average annual sum spent by the student is $1100, this being an increase of $200 a year on the figure for 1920. At the lowest possible estimate, therefore, a medical education must cost at least $5000, and if all the factors, such as pre-medical education, expenses during post-graduate education and loss of potential income from other professions, are taken into consideration the actual cash cost may be more nearly $10,000. The information was obtained by giving expense-books to students and asking them to keep an account of their expenditure. As a result 1253 books were available, and this was reduced to 1161 when married students and students living at home were subtracted. The number is obviously insufficient for more than guarded conclusions. The fees in American universities differ very considerably —from $66 to $610 a year. The average amount expended for books, instruments, and journals also varied widely, from $67 to $189, and the expense for room and board varied from $272 at the University of Illinois to $569 at Harvard. The highest average total cost was $1716 per annum at Dartmouth Medical School, with Harvard a close second, while the lowest reported was $425 at the University of Wisconsin. Apparently at least half the students find time to earn some money while they are working. There seems to be a gradual increase in expense as the student years go by, except that freshmen pay more for their books and instruments. There also seems to have been a steady increase in expense during recent years; tuition and fees, books and instruments now cost over 50 per cent. more than in 1920. On the other hand, the cost of room, board, and clothing has only risen very slightly, and there is a decided decrease in expenses for recreation.

A corresponding study in this country would be of interest. Medical students here suffer greatly from the lack of facilities for earning money in their spare time, and the length and expense of the curriculum is steadily increasing. In an editorial published in the same issue the *Journal of the American Medical Association* doubts very seriously whether it is a sound trend in human life to postpone maturity more and more. The best conditions for reproduction exist before the age of 30, but no member of a profession nowadays has an economic chance of marriage before that age. The editorial further points out that if the sum represented by the cost of a medical education were properly invested for a young man at the age of 20, he would, by the time he was 50, have an income which would maintain him in comfort for the rest of his life. It is a reasonable question whether the average income of the physician represents a proper economic return on the cost of his education. It is easier to point out the difficulties than to suggest their solution. The *Journal* calls for more actual evidence, such as that offered by Dr. Leland, to take the place of arm-chair philosophy and unpractical ideals.

STEREOSCOPIC RADIOGRAPHY.

MEDICAL opinion in this country is divided on the value of stereoscopy in the diagnosis of chest diseases. The tuberculosis experts who made a tour last summer of institutions in Canada and the United States were struck by the reliance there placed upon stereoscopic radiography, and on their initiative the subject came up for full discussion at the Oxford meeting of the Tuberculosis Association reported elsewhere in our columns. Dr. J. B. Christopherson indicated at the outset that the ordinary radiogram of the thorax is a shadowgraph—a picture of a flat area having two dimensions—and that in order to unravel questions of orientation and of relative depth of structures, or to discover the relative position of different parts of the same structure in the chest, resort must be had to screening or to the study of films taken from different angles. The aim of stereoscopic radiography is to introduce the additional factor of solidity or depth. Binocular vision is stereoscopic vision, and stereoscopic vision might be defined as the direct perception of the relative distances of objects. Until, however, two films can be taken simultaneously the success of a stereoscopic picture of the chest will largely depend on the exact maintenance of immobility during exposure, a period of $3^{1}/_{5}$ seconds with the apparatus in use at Victoria Park Hospital. He had found radiostereoscopy of the chest of special value in four conditions: (1) in artificial pneumothorax, for orientating adhesions; (2) in cases where lipiodol is used for investigation; (3) for locating foreign bodies; and (4) for locating cavities in tuberculous lungs. Unsatisfactory stereoscopic effects in chest cases were due as a rule, he thought, to failure in equipment, which more collaboration between clinician, radiologists, and engineer might be expected to eliminate. Dr. Peter Edwards (Cheshire) admitted that stereoscopy had given him a new interpretation of the value of X ray films in his daily work. His routine was to screen *every chest*, and then to decide whether to take a flat or a stereo film. Eight types he selected for the stereo were: (1) one that revealed very little wrong on the screen; (2) one that revealed a foreign body; (3) one that revealed a hydatid; (4) the doubtful silicotic; (5) the artificial pneumothorax case with adhesions, to decide as to thoracoscopy; (6) cases after injection with lipiodol; (7) cases in which there was encysted fluid; (8) cases in which it was essential to localise the lobe in which there was an abscess or bronchiectasis. Moreover, in the stereo one often found early indication of the development of disease which could only be seen in the flat film months later. With good screening and stereos he thought there would be less need for the thoracoscope. With the apparatus he used both exposures could be taken in 0/20 second. *Dr. L. B. Stott (Papworth)* enumerated various possible sources of error in shadow stereography, such as the fact that minute lateral displacements will produce considerable anteroposterior distortion, and the increase or decrease of the stereoscopic effect according to the different degrees of tissue translucency to X rays. The clinician, he thought, was on safer ground in depending upon conscious deduction from anteroposterior and lateral views rather than running the risk of stereoscopic illusion. Many speakers formed a bridge between these extreme views. It was suggested that the conflict might be due, at least in part, to stereoscopic blindness, unsuspected by those who suffered from it.

CLOSING THE HOLE IN CASES OF DETACHED RETINA.

The treatment of detached retina by cauterising the hole has been practised by several ophthalmic surgeons in England during the past year. According to its originator, J. Gonin, of Lausanne, nearly all idiopathic detachments—i.e., those not due to disease, trauma, or tumour—are caused by adhesions between vitreous and retina at the site of old patches of choroiditis, usually in the periphery, not far from the ora serrata. When the vitreous contracts it is liable to pull on the retina at these points and the result may be a tear, through which the fluid in the vitreous chamber enters the subretinal space and causes the detachment. If the tear can be located with sufficient accuracy and can be sealed, the channel through which fluid flows is closed, any remaining fluid is absorbed, and the condition is cured. Gonin is convinced that a hole is formed in every case of spontaneous detachment though it may be very difficult to find, and in some cases impossible owing to opacities in the media. If, however, it can be found, and the detachment is recent, he claims that his operation gives a very good chance of cure, though in view of the uncertainty of exact location and the frequent presence of multiple holes it may have to be repeated several times. In cases of long standing the retina may have lost its function and the prognosis for vision is, of course, much worse.

The first essential in preparation for operation is to localise the hole and this is a very laborious and difficult task. After finding it with the ophthalmoscope the exact spot on the sclera which is over it has to be defined. For this there are two indispensable data—first the exact meridian of the globe in which it is situated, and secondly, the exact distance of the spot on this meridian from the corneal margin. To define the meridian indian ink marks are made just outside the corneal margin in the line which is continuous with that joining the hole with the macula. The distance from the corneal margin is found by estimating the distance from the hole to the ora serrata in disc diameters, one disc diameter being reckoned at 1·5 mm. Add to this 8 mm. for the distance from ora serrata to corneal margin, and if your estimations are accurate you have localised your hole. This is all done before the operation. Now, having reflected the conjunctiva at this spot and made a 2 mm. incision with a Graefe knife through sclera and choroid, Gonin introduces a Paquelin cautery heated to white heat in order to seal the lips of the hole. Others have practised a modified procedure, usually with an electric cautery. R. Rubbrecht, of Bruges, makes an incision 4 or 5 mm. long and passes the cautery rapidly along its whole length in order to make more sure of hitting upon the hole.[1] Sir William Lister[2] points out that the cautery, when once in the subretinal fluid, can no longer retain its heat, and considers it safer not to pierce the choroid but to use the cautery to cause an inflammatory focus in it at the spot opposite the hole, in the hope that the margin of the tear may become adherent to it. Instead of puncturing the sclerotic with a Graefe knife he prefers to make a hole gradually by burning with the galvano-cautery which will block up any vessels which may be divided. Mr. G. W. Black[3] describes the procedure as now carried out at Moorfields Hospital.

> The sclera may be first pierced by a knife, and the interretinal fluid allowed to escape, or the passage through it may be effected by the cautery. The electric cautery with a point of 1 mm. diameter, is used white-hot, and after piercing the sclera it is withdrawn to allow it to recover its heat and then plunged rapidly in and out again to produce scarring of the retina.

Gonin's procedure, however, is apparently unchanged. He lays stress *on the importance of the after-treatment.* The patient is put to bed for a week with his head in such a position that the weight of the vitreous tends to keep the hole closed. If the hole is in the lower part of the fundus the patient may be allowed to sit in an arm-chair a few days after operation. An ophthalmoscopic examination should not be made before the expiration of five days. If not successful the first time the operation may have to be repeated in about a fortnight. Gonin has made as many as six thermo-punctures on the same eye before obtaining a cure, but as a rule one or two suffice. A case was recently shown at the Royal Society of Medicine by Mr. Humphrey Neame where three unsuccessful attempts to close the hole were followed by a fourth successful one with restoration of vision.

Gonin claims to have obtained definite cures in about 60 per cent. of his recent cases, this percentage diminishing with the age of the detachment. Although it is undesirable to encourage hopes doomed to disappointment in the case of old detachments the experience already gained may justify the belief that this operation, or some modification of it, marks a distinct advance in the treatment of this distressing disease. This belief might be considerably strengthened if it were possible to publish details of the condition of patients who had been operated on not less than a year ago. We note that Mr. C. Shapland will read to the Oxford Congress of Ophthalmological Societies later on this month an analysis of 100 cases treated by cautery puncture.

DIPHTHERIA IMMUNISATION.

Our potential control over diphtheria proceeds apace; our actual control will presumably follow in due course. Schick-testing and deliberate immunisation with toxin opened up the possibility of a population made artificially resistant. The use of toxin itself led to some inconvenience and a few disasters, and the discovery that it could be made non-poisonous without losing its immunising power by treatment with dilute formalin was a step of first-rate hygienic importance; this "toxoid" or "anatoxin" is now in general use. Further improvements have lately been introduced by A. T. Glenny and his colleagues[4] at the Wellcome Laboratories at Beckenham. They have found that the active antigenic agent in a solution of toxoid may be precipitated and purified by the addition of potash alum, and that this alum precipitate is decidedly more effective than untreated toxoid in immunisation. The precipitate, for instance, may contain 81 per cent. of the toxoid in the solution, and only 11 per cent. of the total nitrogen, a purification of about seven times. With larger amounts of alum less toxoid is precipitated, but the purification may be as much as 30 times. Tested on animals either experimentally or in the course of the production of therapeutic sera, these alum precipitates make exceptionally good antigens. This appears to be because they are relatively insoluble and remain at the site of injection for a long time, whereas ordinary toxoid in solution is quickly eliminated from the body. In an elegant experiment two lots of guinea-pigs were inoculated intracutaneously, the one with toxoid, the other with alum toxoid. After three days pieces of skin, including the sites of injection, were excised and injected into normal guinea-pigs. The animals receiving the alum toxoid skin became immune, but not those which had the toxoid skin. The facts afford another illustration of the fundamental importance of successive stimulation in immunisation. A primary dose gives the animal experience and, if it effects little by itself, puts it in a position to respond more abundantly to a second dose. Alum toxoid is so insoluble that the animal acquires the necessary training *before* the original dose has been used up. A single dose, therefore, [illegible] may be expected to do as much as two doses of soluble toxoid—plainly a great gain in dealing with the wholesale immunisation of children.

THE LONDON HOSPITAL SERVICE.

It was a happy thought on the part of the promoters of the King's Fund to get together those engaged in many different branches of the hospital service of London, to give them an opportunity to meet each other and to learn each other's points of view. The gathering included representatives of the British Hospitals Association and of its London regional committee, of the Hospital Saturday and Sunday Funds, of the Hospital Saving Association, and of the College of Nursing, as well as of the London County Council. Lord Macmillan, who has acted as chairman of the committee of relations between the voluntary and municipal hospitals in London, remarked that it was a common experience to find, when we come into personal contact with those from whom we have differed at a distance, that we are much more in sympathy with them than we ever suspected. In domestic as in international affairs it was difficult to know where to draw the line between government and liberty, between State control and individual enterprise. Some people, he said, had been foolish enough to say that the passing of the Local Government Act of 1929 sounded the knell of the voluntary system. I do not believe it for a moment, he said amid general applause. The London County Council was far too wise a body not to recognise what a vast asset the voluntary hospitals represent for the community which they govern, and what a burden would be imposed upon them, were they to attempt to supersede the voluntary hospitals. Parliament had made provision for consultation between local authorities and voluntary hospitals and the meetings of the consultative body in London had admittedly been both interesting and helpful. Lord Macmillan concluded by remarking that the voluntary hospital system seemed to answer to a kind of instinct in human nature, and Sir George Hume, an ex-chairman of the London County Council, who followed, said he was as keen as anyone on seeing the voluntary system maintained and encouraged. They were, of course, faced with the need of laboriously putting together an organisation which had been almost lacking; but there must, he said, be consultation at every step, and Section 13 of the Act provided means for the necessary contact. If an example was needed of the Council's attitude, one need only turn to the new Becontree estate near Ilford. Did the London County Council plan there a public hospital at its own expense? No; it was another ex-chairman of the Council who himself took the trouble to organise a new voluntary hospital to be called after King George. The gathering which took place at Mr. Henry Wellcome's invitation in the spacious rooms of the Historical Medical Museum undoubtedly served its immediate purpose of bringing into close touch many different branches of hospital work, and is likely to serve the larger purpos[illegible] reassuring many who have had some anxiety a[illegible] the reality of the proposed coöperation.

The cheap edition of the report of the S[illegible] Committee on Patent Medicines (1914) has been [illegible] of print for some years and, as Mr. Somerville Hast[illegible] elicited from the Treasury representative in [illegible] House of Commons last week, is not likely t[illegible] reprinted. Only the full edition containing proceed[illegible] and evidence is available (H.M. Stationery Of[illegible] [illegible] 7*d.*). We would remind our readers that [illegible] report, along with the text of the 1920 Bill [illegible] printed as a special supplement to THE LANCET of J[illegible] 10th, 1925, of which copies are still available at 2*s.*

In an announcement last week of the proceedin[illegible] of the eighth British Congress of Obstetrics a[illegible] Gynæcology to be held in Glasgow on Wednesd[illegible] April 22nd, and following days, we stated that t[illegible] discussion on the clinical and pathological featu[illegible] of ovarian tumours would be "introduced by Pr[illegible] Blair Bell and Prof. Beckwith Whitehouse from t[illegible] clinical side and Mr. T. G. Stevens from the path[illegible] logical side." Prof. Blair Bell *points out that th[illegible] wording limits him in the discussion to one, th[illegible] clinical, side of the subject, whereas he intends [illegible] deal with both sides.*

THE SERVICES

ROYAL NAVAL VOLUNTEER [illegible] RESERVE.

[illegible]ry, for Haslar Hospital.

Surg. Lt. T. O. Stevenso[illegible] D. R. Hughes to *Victory*, for Haslar Hospital.

Proby. Surg. Sub-Lts [illegible] Reid to *Dorsetshire.*

Surg. Sub-Lt. D. [illegible] and R. G. [illegible] M. Dean to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Capt. [illegible] Boldero resigns his commn. and is granted the rank of Maj.

Capt. [illegible] Y. Eccott to be Maj. (prov.).

TERRITORIAL ARMY.

Lt.-Col. R. Ward to be Bt. Col.

ARMY RESERVE OF OFFICERS.

Lt. G. B. M. Heggs to be Capt.

INDIAN MEDICAL SERVICE.

The undermentioned officers retire: Col. C. C. Murison and Lt.-Col. W. O. Walker.

Lt. P. Shannon to be Capt. (prov.).

Taquid Deen Ahmad (T.C.), Mohammad Jafar, Fateh Mohammad Khan, Dev Datt, Madan Gopal Sainchar, and Saiyad Wasiul Hasan Askari from I.M.S. (T.C.) to be Lts. on Proby.

Manohar Keshav Pandit to be Lt. on Proby.

Lt. C. F. J. Cropper to be Capt.

Col. G. Hutcheson retires.

MODERN TECHNIQUE IN TREATMENT

A Series of Special Articles, contributed by invitation.

CCCXVI.

THE MANAGEMENT OF COLOSTOMY OPENINGS.

It is a great shock to anyone to find that he is obliged to have an artificial opening for the passage of the bowel contents in place of the one provided by nature. But it is quite a mistake to suppose that such an opening will make the patient a permanent invalid, or will prevent him from living an ordinary or active life. Many doctors even seem to be quite unaware of the degree of control over the bowel actions that can be obtained by patients who have a proper modern colostomy opening. They are apt to judge by cases they have seen in the past and especially by cases of inoperable carcinoma treated by colostomy only, often in the last stages of the disease.

Naturally at first, before they have got used to a colostomy, patients are liable to have occasional accidents due to mismanagement; but after a few months, often after a few weeks, they obtain complete confidence, and unexpected actions of the bowel rarely occur except, perhaps, as the result of carelessness. In time they acquire a sense of when the bowel is due to act and have plenty of warning. Many patients who have colostomy openings live very active lives—hunt, play golf, shoot, dance, dine out, travel, and perform all the other activities of a normal person. A little patience and practice are required to learn how best to manage, but once this knowledge is acquired patients should experience little, if any, inconvenience, and no one but themselves and their family need know that they are in any way abnormal.

The following hints for the management of a colostomy opening were written for me by one of my patients who has had such an opening for over four years, and who has, during that period, lived a most active and useful life. I have added to and supplemented his original notes from what other patients have told me, and I think these hints should prove of value to doctors who are consulted by patients with colostomy openings.

Belts and Dressings.

The so-called colostomy belt with a rubber cup is worse than useless—the cup allows a prolapse of the bowel, and the whole arrangement is grossly messy. The best thing is to have a simple, well-fitting abdominal belt for day use and a less stiff one for night. In many cases a shallow cup or flat plate is necessary, but it should not be attached to the belt in any way. The bath belt can be home-made, a strip of thin rubber sheeting about 4 or 5 in. wide, tied with three tapes, or fixed with a catch.

Robinson's cellular wadding (wood wool) is a most perfect absorbent dressing; one roll carefully used may last for ten days or a fortnight. The roll should be cut up into lengths of about 15 in. or more, according to the size of the abdomen, and the cut piece should cover the abdomen. First a graduated pad of this dressing should be placed over the opening and the cut piece laid on and covered with a layer of ordinary cotton-wool; the cotton-wool is to prevent the dressing from fraying. Finally the belt is fastened on. When the dressing is being changed, all the soiled or damp parts should be removed and the remainder kept for redressing. The wood wool can safely be thrown down the lavatory, since it will absorb, but on no account should the cotton-wool be so treated, or it will choke the drains. Cotton-wool should be burnt. When travelling wood wool alone should be used for this reason.

Suggestions for a Normal Day.

On waking up in the morning the patient may, or may not, be conscious of having had an action of the bowels; this probably took place in the early hours. He should not pay any attention to this, but have his *breakfast in bed*; a light breakfast, *hot* tea or coffee, roll and butter, and perhaps an egg and some fish. Then, if he is a smoker, he should smoke and read his paper. In about half an hour he should have the after-breakfast action. The object of having breakfast in bed is to save a dressing. The night belt should then be removed, the excreta cleared away into a pan, a small dry pad and the bath belt applied, and a bath should be taken.

A hot or warm bath is essential, for it is only in this bath that the parts can be thoroughly cleansed. After the patient gets into the bath he should first wash the head, face, and hands, and afterwards the rest of his body; then the belt should be pushed down and the pad removed. The pad should be rinsed and put on one side and all the folds and crevices about the wound very thoroughly cleansed. The pad is then replaced, the belt pulled over again, and the patient gets out of the bath and dries himself. The bath belt and pad are then removed and a dry pad put on and tied across with the day belt.

Normally there should be no further trouble until the dressing is changed again on application of the night belt, but there may be a small action. When changing for dinner, especially if the patient is going out, it is as well for him to look at the dressing and remove any damp or soiled dressings. Whenever the parts are dressed a little powder, such as Johnson and Johnson's "Baby Powder" should be sprinkled on the parts.

Onions in diet may lead to loose actions at odd times. The patient will soon find out for himself what to avoid; fruit with small pips, onions, cream, &c., are generally aperient in action, as also is spinach, and for some people beer and champagne. A capsule of kerol (intestinal) ♏ 3, if taken before breakfast daily, will completely deodorise the excreta.

Diarrhœa.—Should the patient be unfortunate enough to have an attack of real diarrhœa he may have to keep on his back during the attack, and take a dose of the following medicine, repeated in three hours if necessary. One dose is generally enough:—

℞	Bismuth carb.	gr. 40
	Sodii bicarb.	gr. 10
	Tinct. kramer.	dr. ½
	Tinct. camph. co.	♏ 20
	Tinct. card. co.	♏ 20
	Sp. chlorof.	♏ 15
	Aq. menth. pip.	ad oz. 1

Mitte 8 oz.; 1/8th part for a dose.

Where there is *constipation* four or five stewed prunes for dinner will give an action of the bowels about 10 o'clock. Ordinary aperients are rarely necessary.

Most people can keep themselves quite clean and comfortable, and without any fear of accidents, by the foregoing method of management; but a few after a good trial find that the bowel does not act with sufficient regularity. If that is the case the following alternative method of management is recommended. It is the method mainly adopted by working-class patients who have to be at their job early each morning.

Washing-out Method.

After breakfast the patient sits on a chair with a slop-pail or other suitable receptacle between his knees and places a piece of mackintosh so as to drain everything from the colostomy opening into the pail. He then takes a long rubber rectal tube, easily obtained at any chemist, which has been lubricated all over with glycerin or soft soap and passes it into the upper, or business opening. The tube should be pushed in as far as it will go, but on no account should any force be used. After the tube is in place, a piece of wet wool is packed round the tube where it comes through the opening and held firmly in place with the fingers. The free end of the tube is now attached to a douche can or Higginson's syringe, and a water enema of about 2 pints is allowed to flow into the bowel through the tube. This should bring away any excreta that have accumulated in the bowel during the previous 24 hours. If necessary the wash-out can be repeated. The skin round the opening is now cleaned up after removing the tube and dusted with baby powder. The pad and plate are then adjusted and the belt put on. No further action of the bowel should occur until the process is repeated next morning. It is often desirable to wait a few minutes after the wash-out to allow any water to escape before adjusting the pad. Belts with a receptacle for the excreta are often advised by instrument makers, but they are messy and unpleasant and quite unnecessary except in a few very special cases.

If the patient finds the colostomy opening is not behaving as it should, he should consult his doctor or surgeon at once, as he will be able to advise as to what to do. If proper regularity and control cannot be obtained by these methods it is generally due to the colostomy being wrong, badly made, or strictured, and such errors should be corrected by a surgeon.

J. P. LOCKHART-MUMMERY, F.R.C.S. Eng.,
Senior Surgeon, St. Mark's Hospital.

SPECIAL ARTICLES

A SURVEY OF THE IMMUNISATION OF CATTLE AGAINST TUBERCULOSIS.

ATTEMPTS to immunise cattle against tuberculosis have been made by many workers and many methods since the end of last century. The reasons for these efforts are obvious; not only would the protection of cattle against infection with the tubercle bacillus be a sound economic proposition in itself, but it would also contribute materially to the task of ensuring a safe tubercle-free milk-supply. For example, over a period of nine years after the war the number of cows found to be tuberculous in the City of London abattoirs is quoted by Savage[1] as 210, or 33 per cent., whilst statistics show that from 5 to 10 per cent. of milk samples taken in various parts of the country contain virulent tubercle bacilli.

The methods of immunising cattle may be divided into four main groups: (*a*) the use of vaccines made from tuberculin, the various split products of the tubercle bacillus and dead bacilli; (*b*) the use of vaccines of living tubercle bacilli of strains other than bovine—e.g., the tubercle bacillus of cold-blooded animals, avian and human strains; (*c*) the use of vaccines of living bacilli of bovine strain; (*d*) the use of vaccines the precise nature of which has not been divulged.

(A) Dead Vaccines.

This group comprises vaccines made from tuberculin, the various split products of the tubercle bacillus and dead bacilli.

(1) TUBERCULIN.

It is surprising that so few attempts were made during the great tuberculin era at the end of last century to use Koch's old tuberculin as a means of immunisation of cattle. The literature contains only a few short records of experiments, and they are too incomplete to be of very great value. To McFadyean[2] belongs the credit of the first attempt. His first case was a heifer which gave a positive tuberculin test shortly after purchase. In all it received 18 injections with tuberculin with doses rising to 20 c.cm., and was then inoculated intravenously with a gland emulsion, rich in tubercle bacilli, from a horse. Subsequent tuberculin tests were either negative or only f positive, and when the animal was killed three mont afterwards no lesions were found at the post-morte examination except a completely calcified tu in a mesenteric gland. Meanwhile two contro experiments with the test gland emulsion from th horse had resulted in the death of the two animal with typical tuberculosis. McFadyean's second ca was a heifer which gave three positive and on indecisive tuberculin reactions to four test doses 1 c.cm. The animal was then inoculated intr venously with material containing tubercle bacilli o proved virulence. After inoculation this animal wa given eight injections of tuberculin in 10 or 20 c.cm doses. These were followed by six injections o virulent tubercle bacilli. A year after the first inoculation with tubercle bacilli the animal died and tuberculous lesions were found post mortem. A high degree of resistance was evidently present in these two animals, but whether natural or acquired is not clear, and the experiments do not appear to have been repeated. Pearson and Gilliland[3] are also reported to have made an unsuccessful attempt to immunise cattle with tuberculin.

Later Calmette and Guérin[4] attempted the immunisation of two young heifers. The first was given two intravenous injections of 10 c.cm. crude tuberculin at ten days' interval. Thirty days after the second inoculation the animal was given a resistance test injection of 3 mg. bovine tubercle bacilli (strain "Nocard"), and 58 days later it died of acute tuberculosis. The second animal was given two intravenous injections of 20 and 50 cg. respectively of tuberculin precipitated by alcohol, with a ten days' interval between the inoculations. A resistance test, the same in amount as that of the first animal, was then given with the same result—a rapidly fatal tuberculosis. The authors considered that the tuberculin had retarded the fatal result in these two instances, but nothing more. Calmette also quotes Rothe and Bierbaum[5] as having had a similar experience.

All these experiments appear to have been made with Koch's old tuberculin. The present writer cannot find any record in the literature of new tuberculin having been used for the immunisation of cattle. In Calmette's opinion tuberculin has no toxic action on the healthy animal body and therefore has little or no effect in raising resistance.

(2) BACILLARY PRODUCTS.

Since the early work of Vaughan and Wheeler[6] and others on the split products of bacillary substance, many attempts have been made to produce vaccines by treating tubercle bacilli with various substances which break up the bacillus. Foremost of these products are those which result from removal of the whole or part of the waxy envelopes. These vaccines are chiefly lipoid substances. Calmette[7] states that bacilli freed from lipoids by appropriate solvents which do not modify the protoplasmic substances too profoundly can be used as antigens, but that in his hands efforts to employ them as vaccines have been failures. In collaboration with Guérin[4] he experimented with a lipoid made by extracting bovine tubercle bacilli first with boiling acetone and then with benzine. A young heifer was injected intravenously on two occasions with ten days' interval with 100 and 200 mg. of the extract emulsified in bile. Thirty days later a resistance test of 3 mg. bovine tubercle bacilli was administered and the animals died of tuberculosis 24 days afterwards. The experiment was repeated with a younger heifer (two months) with a similar result. The authors therefore concluded that this form of vaccination had absolutely no power of protecting cattle against subsequent test inoculation with virulent bacilli.

It must be noted, however, that Vallée[8] had previously obtained more encouraging results with a vaccine of tubercle bacilli which had been desiccated and extracted with petroleum ether by mechanically shaking for 50 hours in a flask containing glass beads, the bacilli thereby losing a large part of their acid-fastness. Four calves of four months old were used, all being vaccinated by the intravenous route. The first two were given 50 mg. on two occasions with a 20 days' interval. They were given an intravenous resistance test dose of 2 mg. virulent bovine bacilli a month later, and when killed two months after this showed only slight tuberculosis at autopsy as compared with the two controls which had received the same dose resistance test. The third calf was given one dose of vaccine of 200 mg., and the fourth one dose of 400 mg. These two were given a resistance test of 15 cg. virulent bovine bacilli by the intestinal route three months later. Both animals together with the controls were killed at the fifth month. The third animal showed tuberculous glandular lesions equivalent in amount to the controls, but the fourth animal had only three small calcified mesenteric glands. Vallée concluded that these results were not sufficiently promising to warrant further use.

(3) VACCINES OF DEAD BACILLI.

In the early days of tuberculosis immunisation numerous attempts at prophylactic vaccination were made with dead bacilli. Some of these early workers reported abscesses following injection (possibly examples of Koch's phenomenon) and even lesions resembling those of active tuberculosis have been recorded. In one series of experiments Calmette[7] succeeded, however, in causing young guinea-pigs to tolerate the ingestion of very large doses of bacilli, and recently Petroff and Stewart[9] have produced a considerable degree of immunity in guinea-pigs by means of dead bacilli. Loeffler[10] and others have also reported encouraging results. The immunity thus produced, however, is not likely to be permanent.

Only a few of these numerous attempts have been applied to cattle. Vallée[8] tested a vaccine of bovine bacilli heated for one minute to 100° C. Three cows and their calves were used and the experiment was conducted on lines precisely similar to those recorded below with iodised bacilli, all being vaccinated by mouth. Some received a resistance test dose by mouth and were killed five months later, others were placed in a contaminated herd. All developed tuberculosis.

Calmette and Guérin[4] prepared for this purpose a vaccine of bovine bacilli heated for 36 minutes at 65° C. A heifer inoculated intravenously with 20 mg. of this vaccine and then given a resistance test dose of 3 mg. bovine bacilli 30 days later was found at autopsy 90 days after the resistance test to have chronic tuberculosis. Discussing this question later Calmette[7] concludes that the results obtained in this way are nothing more than the modification of an acute rapidly fatal miliary tuberculosis into a chronic slowly progressive tuberculosis. He cites Rothe and Bierbaum[5] as having come to similar conclusions. Immunisation has also been attempted with vaccines of tubercle bacilli killed in various ingenious ways. Thus Vallée[8] used bacilli macerated in iodine water. He cultivated bovine tubercle bacilli in glycerin broth for six weeks and then replaced the broth with iodised water (1 in 400) for one hour. Four bovines were inoculated intravenously with the vaccine thus prepared. The first received 200 mg. vaccine with a resistance test of 3 mg. bovine bacilli 30 days later. This vaccinated animal died of tuberculosis. The second animal received the same vaccinating dose and a resistance test dose of 10 cg. bovine bacilli by mouth. When killed 80 days later no naked-eye lesions of tuberculosis were found, whilst the control showed well-marked mesenteric tuberculosis. The third and fourth animals were given 400 mg. iodised bacillary vaccine followed by a resistance test dose of 15 cg. bovine bacilli by mouth. When killed 148 days later they presented tuberculous lesions of mesenteric glands similar to those of the controls. Vallée next tried vaccinating with iodised bacilli by the mouth. Three cows and their calves were given two doses of the vaccine at 60 days' interval, the cows receiving 50 cg. and the calves 20 cg. of the vaccine when two days old. Four months after the second vaccine one cow and its calf were given a resistance test dose of bovine bacilli by mouth, the cow receiving 20 cg. and the calf 10 cg. Five months later they were killed and found to exhibit tuberculous lesions similar to the controls. The other two cows with their calves were placed, together with the necessary controls, in contact with an infected herd. After a year's contact all the animals, vaccinated and controls, reacted to tuberculin, and when slaughtered were found to have recent tuberculous lesions in the lung with calcified mesenteric glands. Thus the vaccine did not offer much hope of success and was apparently abandoned.

Rappin[11] devised a method of vaccination with which he claimed to have obtained good results in a short series of cattle. The vaccine consisted of bacilli which had been desiccated and then treated with 2–3 per cent. sodium fluoride for several days. After being thus treated the bacilli, according to the author, had lost their power of infecting but still retained their toxicity. Finally the bacilli were exposed to the action of a special antituberculosis serum prepared by the author, so that the vaccine as used for inoculation consisted of an emulsion of bacilli in serum. Calmette[7] states that Rappin's vaccine was tried out by a Commission of the French Society of Comparative Pathology which reported unfavourably.

A vaccine prepared by treating tubercle bacilli with urea has also been placed on the market under the name of Tébéan. Perhaps the best known work on this line, however, is that of Deycke and Much, who have made a very large number of experiments with extracts of tubercle bacilli known as partigens, but we are not aware that any of these have been used for immunising cattle.

Nathan Raw prepared a vaccine from a human strain of *B. tuberculosis* given to him by Koch in 1906 and subcultured since that time. For the purpose of immunising calves a vaccine of heated culture was given in two doses, the first when the calf was a week old and the second a week later. In a publication by Raw in 1925[12] it was stated that 200 calves had been vaccinated in this way, but we are not aware that any subsequent statements as to the results have yet been made.

(B) Living Non-Bovine Vaccines.

The second group comprises vaccines of living tubercle bacilli of strains other than bovine.

(1) TUBERCLE BACILLI DERIVED FROM COLD-BLOODED ANIMALS.

A few attempts have been made to immunise with these strains of the tubercle bacillus—e.g., Dieudonné[13]—but without success. In 1912 Friedmann,[14] however, introduced a vaccine which has had a very considerable vogue as an immunising agent both in man and in cattle. Friedmann's vaccine was prepared from a strain of tubercle bacillus isolated from the lungs of a sea turtle with spontaneously acquired tuberculosis. It was found that this turtle tubercle bacillus did not produce progressive tuberculosis in warm-blooded animals, and it was further claimed by the Friedmann school that it had remained stable from the time it was isolated in 1903 to the time when it was introduced as a vaccine in 1912. In other words, it was a *virus fixe*. Unfortunately a spurious form of this vaccine was placed upon the market shortly before the war, and the whole question has been complicated by acrimonious debates and unreliable statistics from various quarters The most reliable statement in this country will be found in the paper read to the Tuberculosis Association by Dr. Franz Nagelschmidt and reported in our columns.[15] The vaccine is sold in sealed phials in three different strengths: (1) very weak, (2) weak, and (3) strong, and it is said to be free from any additions or modifications.

In 1918 Altmann[16] gave the results of successful experiments performed using this vaccine. He vaccinated a herd of cattle belonging to a farmer who had previously lost about six cattle each year from tuberculosis; after the vaccination of 50 cattle there were no more of such fatalities.

A Commission appointed by the German authorities found that the experience of veterinary surgeons with the Friedmann vaccine was favourable, on the whole, with regard to domestic animals, 42 obtaining good results, 22 doubtful results, and only seven definitely unfavourable results.[17]

(2) AVIAN STRAINS OF BACILLI.

The discovery of the fact that after vaccination of calves with tubercle bacilli of human strain the bacilli might persist in the body of the vaccinated animals for a long time and even subsequently be excreted in the milk, led McFadyean, Sheather, Edwards and Minett[18] to try the effect of living avian tubercle bacilli as a vaccine. As the avian bacillus is only very feebly pathogenic for the human being these authors hoped that the persistence of the bacilli would be a much less serious objection to the use of the vaccine than was the case with a vaccine of human bacilli. McFadyean had previously inoculated two cattle with avian bacilli in 1898 and 1899 and afterwards tested their immunity against bacilli of the bovine type, and although there appeared to be some increase of resistance the animals eventually died of tuberculosis. In the subsequent experiments carried out by all four writers avian cultures from the surface growths of a 5 per cent. glycerin broth were used and 10 to 50 mg. of wet bacilli were inoculated intravenously, the animals being at least three to four months old at the time of vaccination. Nothing that occurred in the course of the experiments afforded any support to the view that a change in type of bacillus could take place. Twenty-nine calves in all were inoculated, 17 being vaccinated with avian bacilli, and 12 as a control with human bacilli. The results showed that the human bacilli were superior to the avian as judged by a subsequent test inoculation with bovine bacilli, but left no doubt in the minds of the writers that avian bacilli could increase the resistance to subsequent infection with bovine bacilli. The experiments did not indicate that there was any real advantage in vaccinating a second time after an interval of two or three months, or that larger doses of bacilli provoked a stronger immunity than the smaller. The experiment was not continued sufficiently long to test the question of the excretion of avian bacilli in the milk of vaccinated animals.

(3) HUMAN STRAINS OF BACILLI.

(*a*) *Behring's Bovovaccine.*—In 1902 Emil v. Behring introduced a method vaccinating cattle against *B. tuberculosis* by a method which he called the jennerisation of cattle, but which is generally referred to nowadays as the bovovaccination of Behring. It consisted in inoculating young calves intravenously with two doses of tubercle bacilli of 4 and of 20 milligrammes, dry weight, respectively. The strain used was one of human origin which had been subcultured for six and a half years until its virulence for the guinea-pig was reduced. The bacilli were dried in vacuo, but were still living. In the earlier experiments the two inoculations of the calf were separated by an interval of six weeks, but later this was extended to three months. Some workers found the method useful, others obtained little immunity thereby, whilst others again found that the immunity though obtainable, did not last more than a year. A careful test of the Behring method was made in France in 1904 by the Société de médecine vétérinaire pratique. Twenty-one calves were given two doses of the vaccine with an interval of 90 days. Two years later Vallée and Rossignol, on behalf of the Société, reported that (1) although quite definite resistance to subsequent injection of virulent bovine bacilli was offered by the animals this resistance was soon exhausted; (2) the resistance of the vaccinated animals to tuberculosis naturally acquired from being stabled with infective animals was not very marked and did not last more than a few months. Subsequent experiments undertaken by the Société showed that the bovovaccine issued by Behring's laboratory at Marburg was not of uniform virulence. Calmette,[19] who gives a full summary of the work, suggests that the variable results obtained by *different* workers were probably attributable to this fact.

(*b*) *Klimmer's Vaccine.*—Klimmer (quoted by Calmette[19]) used a mixed vaccine marketed under the name of antiphymatol, which consisted of human tubercle bacilli attenuated by heating at 52–53° C. until they were no longer pathogenic to the guinea-pig, and of human bacilli which had been passed through salamanders until they were no longer pathogenic for mammals. Resistance is said to have been acquired after two months, but by the end of the year it had diminished. Calmette states that the preparation was tried out on cattle in Saxony by Edelmann with unconvincing results.

(*c*) *Heymans' Vaccine.*—Heymans, also quoted by Calmette,[19] introduced a method of vaccinating cattle by inserting subcutaneously a permeable sac containing modified human tubercle bacilli. The Belgian Government appointed a commission to test out this method on a large scale, but the report of the commission was definitely unfavourable. It concluded that Heymans' sac did not protect animals from infection by ingestion or by contact with naturally infected cattle.

(*d*) *Arloing's Vaccine.*—Arloing, by maintaining tubercle bacilli of a human strain in a vegetative condition in the depth of broth cultures—a method recently revived in a somewhat different form by Dreyer and Vollum—and then gradually elevating the cultures to 44–46° C., succeeded in obtaining a relatively benign strain from which he made a vaccine. He administered this vaccine to cattle in two separate intravenous injections. After a test inoculation with a bovine strain he found that 50 per cent. of his vaccinated animals were at autopsy free from lesions, 25 per cent. had circumscribed glandular lesions, and 25 per cent. lesions of similar intensity to controls. The resistance of vaccinated animals to a prolonged natural infection and the duration of the immunity had not been worked out when Arloing died, but Calmette, who records the experiments,[19] suggests that the immunity produced was probably similar to that of other workers—viz., an immunity lasting about a year and then leaving the animals liable to infection.

(*e*) "*Tauruman*" *Vaccine.*—Koch and Schütz[20] prepared a vaccine of attenuated living human bacilli which was marketed under the name of "Tauruman." Weber and Titze, and Schütz and Holland found that one month after inoculation of the vaccine all the organs of the vaccinated animal were virulent for the guinea-pig, whilst Titze also found that if the vaccine had been inoculated intravenously into cows the organisms might be recovered from the milk. He recovered them as long as 16 months after inoculation. Finally, experiments by Weber and Titze showed that cattle which had been inoculated at the age of three weeks had lost all resistance in nine months, and vaccinated animals living with other animals showed very little resistance. Inoculation of Tauruman, however, appeared, according to Calmette, to dull sensitiveness to tuberculin. He notes also that the calves inoculated are liable to contract a fatal pneumonia after inoculation.

(*f*) The *British Royal Commission on Tuberculosis* also made a short series of experiments with a vaccine of living human tubercle bacilli.[21] Sixteen animals were used in the series; 12 received preliminary vaccinations, 10 with bacilli of human origin, and two with bacilli of bovine origin, and were subsequently tested as to their resistance by the subcutaneous inoculation of a large dose (50 mg.) of bovine tubercle bacilli; four were inoculated with 50 mg. of bovine tubercle bacilli alone and served as controls. Of these four controls three died in from 44 to 76 days of severe general tuberculosis; the fourth was killed after 92 days, and showed general progressive tuberculosis. Seven out of the 12 vaccinated animals were killed in good health 90 to 95 days after the resistance test inoculations, and showed for the most part slight and non-progressive lesions of tuberculosis in the internal organs. Two died after 53 and 87 days from some intercurrent disorder, and were also very slightly affected with tuberculosis. Thus nine out of 12 animals had their resistance so far increased by the protective inoculations that 50 mg. of bovine tubercle bacilli were unable to set up in them progressive tuberculosis. Of the three remaining calves one was killed when well after 89 days and showed general tuberculosis, less severe than that in any of the controls, but more extensive than in the seven just referred to, the lesions in the thorax being apparently progressive. The other two died in 36 and 46 days respectively of acute tuberculosis, differing in some important respects from that produced in the controls; although the lungs were severely affected there were only few tuberculous lesions visible in the other organs.

These experiments clearly show that by the inoculation of large doses of living human tubercle bacilli, as well as by the inoculation of small doses of bovine tubercle bacilli, the resistance of a calf can be raised sufficiently to protect it against the inoculation of a dose of bovine tubercle bacilli which has been shown to be capable of setting up severe and fatal tuberculosis in a calf not so protected. They show further that this degree of resistance is not always produced, and that calves which have been vaccinated once, and even twice, with slightly virulent human bacilli, may develop fatal tuberculosis when inoculated with virulent bovine bacilli.

OBITUARY

JOHN ANDERSON, M.D., B.Sc.Glasg., M.R.C.P.Lond.

WE regret to announce the death, in his fifty-third year, of Dr. John Anderson, head of the division of tropical medicine at the Henry Lester Institute, Shanghai, which occurred in Shanghai on March 28th, after an operation for appendicitis.

John Anderson was born in 1879 at Galston, Ayrshire, and received his education at the University of Glasgow, where he graduated in arts in 1901, became B.Sc. three years later, and in 1906 took the degrees of M.B., Ch.B. He was thus nearly 28 years of age when he graduated in medicine, but the intervening time had been spent in the study of advanced zoology, a branch of science which he at one time contemplated making his lifework. After qualification he went into general practice at Wallasey, and for the seven years preceding the war he led the life of a busy and successful practitioner, becoming a consultant for the surrounding district. At the outbreak of the war he joined up, receiving a commission as Captain, R.A.M.C., in a Welsh Territorial division, and early in 1915 he found himself in the throes of the struggle at Gallipoli, while he distinguished himself in the shambles of Suvla beach. He was later transferred to Egypt, and served in Sinai and Palestine as surgical specialist to casualty clearing stations, until towards the close of 1917 he qualified as a specialist officer in field laboratory work, in which he was engaged until the end of hostilities. After the armistice he remained for two more years as a general consultant in the army, until, in 1920, he decided to follow the study of tropical medicine as a career.

DR. ANDERSON.

Dr. Manson-Bahr supplies us with the following account of Anderson's life as a student of tropical medicine :—

"In 1920 Anderson turned up in London with an ardent desire to specialise in tropical medicine, and undertook a course of study at the London School of Hygiene and Tropical Medicine. In the following year, as Wandsworth Scholar, he accompanied Prof. R. T. Leiper to British Guiana on an intensive research on filariasis, and stayed there nearly a year. He was responsible for the able memoir of that research (Memoir No. 7, London School of Tropical Medicine), and showed a quite unsuspected talent in executing the fine drawings with which it is illustrated. Shortly after the publication of the Memoir, in 1924, he was appointed professor of medicine in Hong-Kong. There he soon showed the stuff he was made of. He completely reorganised and directed the teaching of medicine, and has left an indelible stamp on the medical education of that Crown Colony. At the same time he was in demand as a consultant in the town, and was widely beloved and respected both by the Chinese and the Europeans. In 1929 he resigned his medical chair to organise the Henry Lester Institute of Medicine, Shanghai, for which a sum of over one million sterling had been bequeathed. He spent a busy year in England organising the work and planning the Institute, and did not arrive in Shanghai until late in 1930. He was engaged in intensive research in the local diseases at the time of his death.

"John Anderson will long be remembered by his friends for his self-effacing courage, for his devotion to duty, his kindly, quiet sympathetic manner, and for his peculiar talent for getting the best out of all kinds of men. In China this was an asset without price, for he made a lasting impression upon the mind of every Chinaman he came in contact with. During the war he is known to have performed deeds of valour which received no official recognition—for instance, during a raid on a casualty clearing station at Belah, Palestine, in July, 1917, he remained operating on a patient when a bomb exploded on the tent. His former colleagues at the London School of Hygiene and Tropical Medicine mourn his loss as a sincere student, and one with whom it was hoped that closer contact would have been established in the near future."

WILLIAM CARMICHAEL McINTOSH, M.D., LL.D. Edin., F.R.S.,

EMERITUS PROFESSOR OF NATURAL HISTORY IN THE UNIVERSITY OF ST. ANDREWS.

Prof. McIntosh, the doyen of medical zoologist of Scotland, possibly of Britain, who died at hi residence at St. Andrews in the ninety-third year o his age, was well known among scientists throughou the world for his work in marine biology.

Born at St. Andrews on Oct. 10th, 1838, McIntos was educated at Madras College in that city and th University, before entering the University of Edinburgh, where he graduated in 1860, obtaining a g medal for a thesis on Observations and Experimen on the Shore Crab. Although his bent was early declared, he entered upon asylum practice, from 1860 to 1863 was assistant physician at Murray Royal Asylum, Perth, when he was elected superintendent of Murthly Asylum. During th period he found time to pursue zoological studies and in 1869 was awarded the Neill gold medal of th Royal Society of Edinburgh for investigatio chiefly in the subject of marine biology. In 1882 was unanimously appointed to the chair of na history at St. Andrew's University, and in the following year made a report for the Royal Commission o Trawling which brought him considerable credi His name, however, will be best remembered throug the natural history museum of his University and h connexion with the Gatty Marine Laboratory, the fi marine laboratory in Britain, of which he was directo He was not a voluminous writer and his outp dealt wholly with his own subjects.

Prof. McIntosh, who was unmarried, was abstainer from alcohol and tobacco, and pr his physical and mental activity until the close his long life ; in spite of his advanced age, some thr weeks ago he undertook a railway journey to Lond to attend a scientific meeting, and it was a chill caught on the return journey which developed into pneumonia and caused his death.

SPENCER STAWELL CROSSE, *M.C.*, M.R.C.S.Eng.

Dr. Spencer Crosse, who died at Kudat, British North Borneo, on Feb. 10th, was the third son of the late Rev. Edward Albert Crosse, and was born at Long Wittenham, Berks, in 1888. He was educated at Clifton College and at Pembroke College, Cambridge, completing his medical curriculum at Guy's Hospital. He took his B.A. in 1909, and qualified as M.R.C.S. in 1912. After serving as house surgeon and house physician at the Royal Berkshire Hospital, he joined the Royal Army Medical Corps in the first week of the war. During the greater part of the war he was on active service in France, chiefly with field ambulances or at casualty clearing stations, and received the Military Cross. At the close of the war he remained in the army for another six years, and was stationed in India for the greater part of this period. On leaving the army he held various posts as medical officer in the tropics, on the Gold Coast, in British Guiana, and Borneo. He took the Diploma of Tropical Medicine in 1928, shortly before sailing for Borneo on his last appointment.

A colleague writes: "A straight man in all his dealings, Spencer Crosse was greatly beloved by all who knew him. Of an easy-going temperament, he took the ups and downs of life in a true philosophical spirit. He was kind and tolerant, and always endeavoured to put the best interpretation on the actions of others. He was never pushful, according to modern ideas, and, though he had brains above the average, he preferred to exercise them in what immediately lay before him."

JOHN EDWARD THOMAS, M.D. Edin., J.P.

Dr. J. E. Thomas, who died at his home Nantlys, Bangor, on March 24th, was one of the best known practitioners in North Wales. The second son of the late Mr. W. Thomas, of Plas Newydd, near Holywell, he was educated at the University of Wales, Aberystwyth, and Edinburgh University, where he graduated M.B. in 1890, proceeding to the M.D. in 1900. After a period as house surgeon to the Caernarvonshire and Anglesey Infirmary, where he was later to give many years of devoted and enthusiastic service, he settled in Bangor, and soon established a large practice in the town and surrounding district. From his earliest days he had shown aptitude for surgery, and his appointment in 1910 as surgeon to the Caernarvonshire and Anglesey Infirmary marked the beginning of a new era in the surgical work of this hospital. At the end of his 20 years' tenure of office, the hospital committee, as a mark of their appreciation of his work, took the unusual step of inviting him to continue as senior surgeon. During the whole of the war Dr. Thomas was surgeon to the Military Hospital at Bangor. His reputation as a surgeon was such that for many years his colleagues throughout North-West Wales availed themselves fully of his experience and operative skill. His surgical appointments included those of consulting surgeon to the Blaenau Festiniog and Portmadoc war memorial hospitals. He was a member of the court of governors of the University College of North Wales, and was medical officer to this College and to the Bangor Normal College. Though his large general and consulting practice kept him very busy he found time for public work as well. He was an alderman of the corporation of Bangor and was mayor of the city in 1920–21. He was a justice of the peace for the county of Caernarvon and sat regularly on the bench. He is survived by his widow, three daughters, and one son, Mr. T. Meyrick Thomas, F.R.C.S.

EDWARD WILLIAM WOOD WHITE, M.D. Dub.

Mr. Wood White, who died on March 22nd at Birmingham at the age of 76, was of Irish descent and was born in Ireland. He was a graduate of Trinity College, Dublin, proceeding to the degrees of B.A. in 1875, M.B. in 1877, and M.D. in 1893. Subsequently he studied at the London Hospital and was for three months house surgeon to Mr. Jonathan Hutchinson. His experience there it was that probably decided him to pursue ophthalmology. In 1879 he was appointed house surgeon to the Birmingham Eye Hospital, a position he held for five years, and at the end of which time he was elected honorary surgeon to the hospital, an office he discharged punctiliously and with great success until his retirement in 1910, when he became a consulting surgeon. He secured the confidence of his professional brethren and of the public alike, and had a successful career in his specialty. He took his share in the work of the local medical societies, was honorary secretary for some years of the Medical Institute, and served as president of the Midland Medical Society. On five occasions he delivered the Middlemore Lectures in Ophthalmology, his subjects being eye symptoms in diseases of the general nervous system, corneal ulcers and their treatment, inflammation of the conjunctiva, glaucoma, and injuries to the eye-ball and its neighbourhood; but apart from these he made few contributions to medical literature. Some years ago increasing deafness led to his retirement from practice, and for the last few years of his life he suffered from cardiac disability due to high blood pressure. "He met his distresses," writes a colleague "with high courage and patience, and after months of anxious illness he regained some activity and actually resumed golf, for which he had great enthusiasm. For many years he was a keen lawn-tennis player, and acquired considerable skill in the game. Those of his contemporaries who remain remember Wood White with great affection, not only as a skilful ophthalmologist, but as a courteous gentleman and a loyal friend."

THOMAS REDMAYNE, M.B. Camb., F.R.C.S. Eng.

WE have to record the death of Mr. Thomas Redmayne on April 1st at St. Leonards-on-Sea at the age of 67. A son of the late Mr. R. R. Redmayne, of Newcastle-upon-Tyne, he was educated at Repton School and Trinity College, Cambridge, where he was an exhibitioner. After taking a second class in the Natural Sciences Tripos he went to the London Hospital whence he qualified as M.R.C.S. in 1886. After serving as house surgeon, house physician, and receiving-room officer, and going abroad as a ship's surgeon, he became F.R.C.S. in 1889 and settled in practice at Gateshead. Later moving to St. Leonards-on-Sea he became assistant surgeon to the Royal East Sussex Hospital, Hastings, which institution he served for 34 years, succeeding Dr. Cecil Christopherson as senior surgeon. He was also chairman of the medical committee of the hospital and had a large surgical practice in the locality. In leisure time he was interested in golf, fishing, climbing, and music.

Mr. Redmayne was at one time president of the East Sussex Medico-Chirurgical Society. He leaves a widow with two daughters. A son died at an early age.

PUBLIC HEALTH SERVICES

MENTAL TREATMENT ACT, 1930.

THE PROVISION OF TEMPORARY TREATMENT.

BY JOHN P. STEEL, M.D. EDIN.,
DEPUTY MEDICAL SUPERINTENDENT, ST. LUKE'S HOSPITAL, MIDDLESBROUGH.

WHILST the Act has not been in force for a sufficient length of time to allow the full benefit therefrom, it is evident that it will go a long way towards the attainment of its end, which is the prevention of certification of recoverable cases. The extension of the voluntary boarder system will, when the terms of the Act become more readily carried out, help to prevent the borderline case; provision of temporary treatment without certification should ensure that none but the chronic case reaches the mental hospital proper. At present the Act is likely to be accepted in part rather than as a whole, because the accommodation for patients suffering from mental instability is somewhat limited outside the mental hospital, and until this is remedied the full benefit of the new regulations are not available. To the ordinary person it does not matter whether a patient is admitted to the mental hospital as a voluntary boarder or under recommendation for temporary treatment; once they have been in a mental hospital they are labelled as having been "insane."

The ideal combination of circumstances is to have clinics at the ordinary hospitals (many of course being already in operation) with observation wards attached, and where this is possible the patient can be observed for a reasonable time so that a considered decision and diagnosis can be given, and full advantage can be taken of specialist examination in the hospital. If, after careful consideration and treatment, the case is deemed unsuitable for the observation ward, then the next step should be a half-way one to the mental hospital—viz., to an institution entirely and completely detached from the mental hospital, and with no administrative connexion therewith. In this place there should be no reason for the withholding of the more specialised treatments presently found in the mental hospitals proper, and in this half-way house it would seem probable that the voluntary boarders and the recovering patients under temporary treatment without certification would recover (where recovery is probable) without recourse to the mental hospital at all.

Naturally this is the ideal—but few municipalities or counties are yet equipped for such methods. As an alternative, and until the provisions of the Act make buildings of the type possible, there is the municipal hospital with the "observation" ward. Patients recommended for temporary treatment can be accommodated in this way, and there is not the same stigma attached to residence in such a hospital as there is to a similar stay in a mental hospital; for although the Act does away with the term "asylum," it will remain in force in conversation for a long time to come, and will convey the impression of "lunacy" just as it always has done. The main difficulty lies in the shortage of suitable accommodation at the general hospital, and the dislike on the part of the patient to be considered a "mental" case. The provision of suitable accommodation in the municipal hospital, or the provision of separate hospitals altogether, will quickly overcome this dislike; at the clinics already in operation it is not found that patients object to general hospital methods, and these clinics are able to obtain a percentage of true borderline cases. Until some suitabl hospital or series of wards are provided as a separat entity, the part of the Act dealing with volunta boarders and temporary treatment without certification will not be as beneficial as it might.

Steps are being taken by some municipal authoritie to appoint medical officers in charge of the mental services, a step in the right direction provided tha those appointed have reasonable power to enforce their recommendations for preliminary treatment. If this is not provided then it will be quite possible for a medical officer to see a case at a municipal (or general) hospital and to make suggestions for treatment which will in his opinion clear up the cas without recourse to certification. If he has not th authority to see that these methods are carried ou he may be chagrined to receive intimation by the next post that the case has been certified, and a request for allocation to a mental hospital. Under such circumstances his appointment is a waste o money and a stultification of the meaning of the Act.

The whole purpose of the Act is to endeavour to keep cases out of the mental hospitals; at presen there are few suitable places where recoverable case can be treated except in the mental hospitals, and i will mean the expenditure of very large sums t provide such places.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDE MARCH 28TH, 1931.

Notifications.—The following cases of infectiou disease were notified during the week: Small-pox, 220 scarlet fever, 1500; diphtheria, 979; enteric feve 24; pneumonia, 2012; puerperal fever, 51; puerper pyrexia, 148; cerebro-spinal fever, 66 (last week 84) acute poliomyelitis, 6; acute polio-encephalitis, 2 encephalitis lethargica, 12; dysentery, 6; ophthalm neonatorum, 108. No case of cholera, plague, c typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of th London County Council on March 31st–April 1st was a follows: Small-pox, 224 under treatment, 2 under observation (last week 231 and 10 respectively); scarlet fever, 1277 diphtheria, 1676; enteric fever, 125; measles, 133 whooping-cough, 441; puerperal fever, 29 (plus 14 babies encephalitis lethargica, 122; poliomyelitis, 2; "oth diseases" 187. At St. Margaret's Hospital there we 14 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, includi London, there was no death from small-pox, 1 (from enteric fever, 60 (1) from measles, 9 (1) fro scarlet fever, 46 (11) from whooping-cough, 30 (from diphtheria, 72 (16) from diarrhœa and enterit under two years, and 301 (42) from influenza. Th figures in parentheses are those for London itself.

Five deaths from meningococcal meningitis occurred London, 1 from 1–2 years, 2 from 2–5 years, and 1 ea from 15–25 and 35–45 years. Fifteen fatal cases of meas were reported from Liverpool, 10 from Birmingham, 4 fro Newcastle-on-Tyne. Salford reported 4 deaths fro whooping-cough, Manchester 3. Diphtheria claimed victims at Leeds. The 259 fatal cases of influenza outs London are scattered over 82 great towns: 20 were report from Sheffield, 11 each from Stoke-on-Trent, Manchest and Leeds, 10 each from Bristol and Birmingham.

The number of stillbirths notified during the we was 305 (corresponding to a rate of 45 per 1000 births including 45 in London.

CORRESPONDENCE

TREATMENT OF RHEUMATOID ARTHRITIS.

To the Editor of THE LANCET.

SIR,—There is much in Dr. Douthwaite's paper in your last issue (p. 785) that is valuable to all interested in rheumatoid arthritis, but his opinion concerning the value of vaccines is open to discussion. By vaccines I presume he means not only the simple suspensions but also residual vaccines in which I am chiefly interested, and I suppose his criticism must apply to this type equally. I have published records of treatment with autogenous residual vaccines in selected cases and the results were assessed by other observers. Further, the series was consecutive and contained all the failures. The proportion of cases which benefited was high and the only selection made was bacteriological. I refused vaccine treatment to all cases in which I did not find satisfactory evidence of streptococcal infection in the throat, teeth, tonsils, bowel, or other focus.

Dr. Douthwaite's criticism of vaccines is destroyed by his subsequent statement that protein shock is useful. If vaccines have no specific action then they must act as foreign proteins if at all. It follows from that inference that whilst vaccines may be useful if they are regarded as being made from a specific organism they cannot conceivably be useless when non-specific bacterial proteins are claimed as valuable. In discussions on the relative merits of vaccines and protein shock the supporters of the latter rarely show any appreciation of the two-edged nature of the weapon that they use as an argument. I should like to make clear that my remarks are confined to those cases in which a vaccine is bacteriologically feasible. In my experience they form about half of all cases.

I agree with Dr. Douthwaite that osteo-arthritis is in every way distinct from rheumatoid arthritis. I believe that a large proportion of the latter disease is due to a streptococcus, but from a number of stray items of observation I suspect a staphylococcus as the possible cause of osteo-arthritis. Most observers will agree that the causal organism is not found in the affected area but that the lesions are due to bacterial products carried from some remote focus. In my hands residual vaccines have been more successful than any other form of treatment in the first stage of the disease whilst the patient's potential resistance is still good.

In his excellent clinical description Dr. Douthwaite omits to mention a sign that I have found common in young women when the streptococcal infection, if ascertainable, lies in the throat; the pharynx and pillars of the fauces are bright red and apparently dry, standing out in sharp contrast to the pale buccal mucosa. The tonsils are frequently not enlarged and the toxic products seem to be absorbed from the inflamed area at large.

I am, Sir, yours faithfully,

Manchester, April 6th, 1931. C. E. JENKINS.

(*Continued from previous page.*)

PROVISIONAL DEATH-RATES FOR 1930.

The Registrar-General announces provisional death-rates from certain specified diseases per million population for England and Wales during the year 1930 as follows:—

	Males.	Females.	Persons.
Respiratory tuberculosis ..	863	624	739
Other tuberculosis	174	145	159
Cancer	1411	1404	1454

The maternal mortality per 1000 live births based on deaths primarily classed to puerperal conditions was as follows:—

Puerperal sepsis	1·92
Other accidents and diseases of pregnancy and parturition	2·48
	4·40

OVERCROWDING AS A FACTOR IN OUTBREAKS OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—Prof. Sheldon Dudley, in his first Milroy lecture published in THE LANCET of March 7th, refers to the seeming paradox of the incidence of cerebro-spinal fever in naval boys' training establishments being 30 times greater than in sea-going squadrons; and, as an explanation of this, he mentions the hypothesis that naval recruits obtain a certain immunity against the disease by contact with carriers in the training depôts. Another explanation might be found in the earlier part of the same lecture, where Prof. Dudley states that the ventilation of the modern fighting ship could scarcely be bettered; and describes how, in the sleeping quarters of one ship, despite "the densest overcrowding" there was an almost complete absence of accumulation of atmospheric moisture as a result of the perfected system of ventilation adopted.

It is, I think, in the light of such facts that the 64 cases of cerebro-spinal fever which, according to Prof. Dudley, occurred in the fleet at sea during the whole period of the war must be regarded. This amazingly satisfactory record might indeed be taken as an argument against the importance of overcrowding as a factor in the production of outbreaks of cerebro-spinal fever, if the overcrowding implied is in the sense of deficient *cubic space*, as defined as a principle of investigation by Glover, to whose work in this connexion Prof. Dudley more than once alludes. Overcrowding, as I have been led to regard it in my own specialised work on the disease during the years 1915–1919, is wholly bound up with the question of atmospheric humidity, especially *indoor humidity* in sleeping quarters; and the conclusions embodied in my reports to the War Office and in various published papers[1 2 3] are, I venture to think, further substantiated by the evidence which Prof. Dudley has now brought to bear on the subject. The war period record of the fleet in connexion with cerebro-spinal meningitis can, at all events, be regarded as something more than coincidental testimony to the efficiency of proper ventilation amid conditions in which, to use Prof. Dudley's own words, the density of population reached the "maximum possible," and any "spacing out of beds" as advocated by Glover was an obvious impossibility.

I may recall briefly the main features of the cosmic hypothesis advanced by me in 1915,[1 4 5] and more fully developed during the years 1916–1917. Atmospheric humidity—more especially *indoor humidity* operating through overcrowding and insufficient ventilation[3 9]—constitutes a cosmic factor which favours outbreaks of the disease, the meningococcus being about. This hypothesis, based on ample experimental evidence, affords a reasonable interpretation of the advent of "cases"—viz., that humidity acts by causing congestion and œdema of the naso-pharyngeal mucous membrane, thereby permitting the meningococcus of the "carrier" to penetrate this barrier.[8] Also, it explains how (even in the absence of "spacing out") better ventilation combats overcrowding, by its beneficent action on indoor humidity. The temperature indoors being always higher than that out-of-doors, it follows that when the colder outdoor air (even though saturated) penetrates indoors, through efficient ventilation, it loses much of its saturation. It becomes then less inductive of naso-pharyngeal œdema, thereby diminishing the risk of the meningococcus of the "carrier" migrating to the meninges to produce a "case." [6][9] It will be noted, on this hypothesis, that if the meningococcus is not about, the degree of humidity becomes of no importance, since cases of cerebro-spinal fever cannot then occur. This gives, I think, some point to the opinion of Prof. Dudley that "the importance of air supply per se in the prevention of disease has perhaps been overstressed," if by this he presupposes that pathogenic bacteria are not about. Prof. Dudley's contention here seems to me to express but a particular aspect of the more general truth embodied in the cosmic hypothesis put forward by me.

An interesting question arises. What is it that rids the carrier of his meningococcus at sea? I had formerly assumed in my own work ashore that three meteorological factors dominated the situation: absence of atmospheric saturation, unequable condition of temperature, and presence of sunshine (all three of which are interconnected [2, 8]); and that seemed to constitute a good enough working hypothesis then, for I had often noticed that carrier-rates in carrier isolation camps quickly improved with the arrival of sunshine and resulting outdoor life. It is possible that the beneficial action of these same factors are accentuated at sea.

In brief, then, it does appear to me that Prof. Dudley's evidence abundantly confirms the established ideas which I have formed as the result of my own observations and experimental work. Assuming the best atmospheric conditions in the fleet below decks, it would seem that we can dispense with the sunshine, and trace the navy's comparative freedom from cerebro-spinal fever to the absence of that atmospheric moisture which enabled me during the war period to predict, with more or less assurance, the imminence of "cases." I am, Sir, yours faithfully,

Alexandria, Egypt, March 24th, 1931. A. COMPTON.

POLYVALENT NATURAL ANTIBODY.

To the Editor of THE LANCET.

SIR,—For many years I have been working on the possibility of making use of the bactericidal powers of normal blood-serum. The steps have been described in medical and veterinary journals commencing in THE LANCET (1924, i., 431), and in conjunction with my clinical co-workers, summarised in the *Medical World* (April 11th to May 2nd, 1930). The demand for the various therapeutic combinations became so great that the possibility of manufacture on a large scale had to be considered. It is obviously of vital importance that the antibody combinations must be accurately made and standardised. I know from long experience how slight an error will yield a comparatively inert compound as regards antibacterial action, both in vitro and clinically. Unless the antibody combinations reach the highest standard of accuracy they will tend to discredit a scientific principle that I am sure is sound. For about a year, under the names Edwenil, Davenil, and Globenil, and accompanied by some of my medical bibliography, E. H. Spicer & Co., Ltd. have been offering to the profession these biochemical preparations based on my work. After this date I wish it to be definitely known that I have no further association whatsoever with E. H. Spicer & Co., Ltd., or the manufacture of their products.

I am, Sir, yours faithfully,

Leamington Spa, April 6th, 1931. S. G. BILLINGTON.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

EASTER ADJOURNMENT.

THE House of Commons adjourned on Thursday, April 2nd, for the Easter recess until Tuesday, April 14th.

BETHLEM ROYAL HOSPITAL.

On March 31st the House of Commons considered the Civil Estimates in Committee.

On a vote for £318,200 for expenditure on art and science buildings in Great Britain, Mr. C. WILLIAMS called attention to an item headed "Bethlem Royal Hospital, adaptation for Imperial War Museum." He said that that represented £50,000, which was a very large sum, and the committee were entitled to know precisely what was being done to the hospital.

Mr. LANSBURY (First Commissioner of Works), in reply, said that the public of London were grateful to Lord Rothermere for making it possible for the Government to take over that fine estate. Originally it was proposed to pull down the whole building, but it had now been decided that the War Museum in the Western Galleries adjoining the Imperial Institut should be transferred. The L.C.C. would have t bring in a Bill to obtain powers from Parliament t alter the original Act for dealing with the Bethle Hospital. Lord Rothermere and the L.C.C. ha agreed, and the Government were now asking th House to agree to a proposal to use one portion o Bethlem Hospital to house the War Museum. A 999 years' lease was being negotiated at £1 a yea to carry out this object. Replying to Mr. Kell Mr. Lansbury said no money had yet been spent o adapting the buildings. £5000 had been voted, bu the Government would not spend one penny unt it was quite certain that the Museum would b moved there. It was practically certain that i would be so. The vote was agreed to.

VENTILATION OF HOUSES OF PARLIAMENT

On a vote for £78,430 for expenditure on the House of Parliament, Miss WILKINSON asked if anything was being spent on improving the antiquated system of ventilation. The sickness-rate and even the death-rate among Members of Parliament had been very high in the past few months. The sickness-rate had been specially high, and all of them felt that when they came into the House they were entering a building where no fresh air seemed to enter at all. She understood that the system, which was experimental when first put in, was now admitted by every kind of expert to be antiquated. The air came up through the gratings on the floor and passed their dusty boots before it got to their nostrils; there was no fresh air coming in anywhere. It was disgusting to think that the air they had to breathe came welling up through the gratings in the floor. She was told that the air was supposed to be purified and washed before it got to Members, but even if that were wholly scientific and wholly true the air would be contaminated by the dust of the streets which was presumably on their boots. The difficulty was that the cleaning of the air was not effectively done. In the early afternoon fumes were often drawn into the chamber. The air was drawn from the surface of the Thames, washed and pumped through to Members. It was possible to tell when a tug was passing and dipped its funnels to go under the bridge, for Members got the heavy smoke from it, and obviously other impurities as well. The ventilation system was put in before there were so many petrol fumes on the Thames. Now the fumes rested on the water and were drawn into the House, and presumably contained carbon monoxide as well. The atmosphere was getting steadily worse, and something should be done. The system of ventilation needed modernising. The inventions of modern science ought to be used to bring up to date the House where they had to spend a large part of their working life.

Mr. STRAUSS supported Miss Wilkinson's complaint, and said that the atmosphere of the House and the precincts was enervating. It was so heavy, so devitalising, that most people suffered from headaches and found it almost impossible to concentrate on their work.

Mr. LANSBURY said that he did not understand the criticisms in regard to the atmosphere of the House. He had read most of the reports. They all disagreed with one another, and the experts that he had consulted all contradicted one another. A committee was appointed recently on the subject, and they reported that such defects as existed in the ventilation were attributable to the methods of distributing the air current and not to the quality of the air admitted, which was both chemically and bacteriologically pure. Miss Wilkinson had said that he breathed poison all the time that he sat on the Government bench, because the air was coming through the floor over his dirty boots. Experts who had examined the air told him that it was pure.

Dr. HASTINGS asked if the examination was made when the House was sitting?

Mr. LANSBURY said that all he knew was that the committee reported in 1905. In 1923 another committee made certain recommendations, the important part of which had been carried out. Further works suggested could be carried out for £5000, but the difficulty was that people were not agreed that when that sum had been spent they would have done what Members thought was right. He did not want to spend money unnecessarily, but if it could be proved that the health of Members really was in danger by lack of proper ventilation, the department, if it was instructed to do so, would be only too glad to take more advice—they had taken a lot already—to see if they could get the experts to agree.

The vote was agreed to.

HOUSE OF COMMONS.

TUESDAY, MARCH 31ST.

Hospital Sweepstakes.

Mr. TOOLE asked the Prime Minister whether, in view of the extent to which people in this country took part in the Irish Free State sweepstakes, as revealed by the results of the draw, the Government could see their way to introduce legislation to enable similar sweepstakes to be conducted in this country to aid hospitals in need of funds.—Mr. CLYNES replied: Apart from any other consideration, I have yet to learn that the hospital authorities desire such legislation.

Washington Hours Convention.

Sir THOMAS INSKIP asked the Minister of Labour whether she had ascertained that the conditions upon which France and Italy respectively ratified the Washington Hours Convention would be satisfied, so far as Great Britain was concerned, by ratification by His Majesty's Government subject to the provisions of the Hours of Industrial Employment Bill.—Miss BONDFIELD replied: The condition attached by France is ratification by Germany and Great Britain. The condition attached by Italy is ratification by Belgium, France, Germany, Great Britain, and Switzerland. I am unaware of any other conditions.

Sir THOMAS INSKIP asked the Minister of Labour whether Germany had taken any steps to ratify the Washington Hours Convention.—Miss BONDFIELD replied: I understand that legislation intended to enable the German Government to ratify the Convention is under consideration.

WEDNESDAY, APRIL 1ST.

Report of Hedley Committee.

Lieut.-Colonel FREMANTLE asked the Minister of Health whether the Hedley Committee, appointed by the Board of Control, had completed their report; and, if so, when it would be published.—Mr. GREENWOOD replied: I understand that this report will be presented to the Board shortly after Easter, and the question of publication will then be taken into immediate consideration.

Rubber Paving Round Hospitals.

Mr. GRAHAM WHITE asked the Minister of Transport if, in view of the opportunity afforded by the low price of rubber, he would, where possible, direct and elsewhere recommend that the roadways immediately around urban hospitals be covered with a rubber surface.—Mr. H. MORRISON replied: I understand there has been a considerable reduction in the price of rubber paving blocks, but that the cost is still relatively high. Local authorities are in the best position to judge of the circumstances which should govern the choice of paving materials, and I do not think it would be appropriate for me to exert pressure on them in the direction which the hon. Member suggests.

Birth Control Literature.

Sir JAMES REYNOLDS asked the Postmaster-General if his attention had been drawn to the extensive use of the post for the dissemination of birth-control literature; and if he would take further steps to prohibit such use of the post.—Mr. VIANT (Assistant Postmaster-General) replied: My attention has been drawn to the fact that such literature is sent by post, but I am advised that, unless the language used is indecent or obscene, I have no power to prohibit the transmission of such matter by post.

THURSDAY, APRIL 2ND.

Infant Mortality.

Mr. DAGGAR asked the Secretary of State for Scotland the number of children under the age of 12 months who died in Scotland during 1930.—Mr. ADAMSON replied: The number of children under the age of 12 months who died in Scotland in 1930 was 7851, which represents an infantile mortality-rate of 83 per 1000.

Blind Persons.

Dr. FORGAN asked the Minister of Health the latest estimate of the number of totally blind persons in England and Wales.—Mr. GREENWOOD replied: I have no information as to the number of totally blind persons in England and Wales, but the number registered as blind within the meaning of the Blind Persons Act, 1920, was 52,727 on March 31st, 1929, the latest date for which figures are at present available.

Workmen's Compensation Medical Appeals.

Mr. LAWTHER asked the Home Secretary the number of cases referred to the medical referees under the Workmen's Compensation Act in the mining industry in Durham for 1928, 1929, and 1930; and the percentage for and against the workmen.—Mr. CLYNES replied: The total number of cases so referred was in 1928, 590; in 1929, 544; and in 1930, 746. I am unable to give the information asked for in the latter part of the question, except as regards cases of industrial disease, where there was an appeal from the decision of the certifying surgeon under Section 43 (1) (f) of the Act. These cases numbered 58, 44, and 62 in 1928, 1929, and 1930 respectively. The percentage of these cases decided in favour of the workman during the three years' period was 68.

Mr. McKINLAY asked the Home Secretary if he was aware of the grave dissatisfaction in Scotland caused by the attitude of the medical referees under the Workmen's Compensation Act; and whether he would appoint a small committee to survey the decisions of such referees with a view to rectifying a long-standing complaint.—Mr. CLYNES replied: I have received complaints as to several of the medical referees appointed for Lanarkshire, but the allegations have been of a general character, to the effect that the referees are biased against the workmen, and that their decisions are unfair, and they have not been supported by evidence. Particulars of only three cases in which it was alleged that the workman had been unjustly treated have been submitted; and while I am not in a position to review the decisions of referees, I have carefully examined these particulars, and cannot find anything in them to sustain such a charge. Great pains are taken to appoint as referees doctors of the highest possible standing and professional qualifications; and once a person is appointed to a judicial post of this kind he is entitled to expect that the Home Secretary will not countenance charges of unfairness except on clear and definite evidence of incompetence or bias. A general survey of the kind mentioned in the question, even if practicable, would not in the circumstances be justified.

MEDICAL NEWS

University of Aberdeen.

On April 1st the honorary degree of Doctor of Laws was conferred among others in Sir Leonard Hill, M.B., F.R.S. and Dr. C. R. Marshall, emeritus professor of materia medica in the University. Ordinary degrees and diplomas were conferred on the following:—

M.D.—N. M. Munro (awarded commendation for thesis) A. G. Morison, W. E. Morrison, and J. B. Samson.

M.B., Ch.B.—H. W. Fullerton (with First-class Honours), J. A. Birnie, S. A. B. Black, D. S. Cochran, W. L. Donaldson, G. MacN. R. Duffus, I. R. G. Galloway, W. H. Gossip, R. D. Henderson, J. W. Levack, Hugh Livingston, E. O. Low, D. S. Macdonald, J. B. Macfarlane, J. S. B. Mackay, T. A. Morrison, R. G. Russell, W. R. Scott; J. M. Stuart, A. G. D. Whyte, and R. D. B. Wright.

D.P.H.—E. A. Johnston, S. S. Proctor, and J. C. Sleigh.

Congress of Tropical Medicine.

The second International Congress of Tropical Medicine will be held at Amsterdam from Sept. 12th to 17th under the presidency of Prof. G. Grijns. The subjects of discussion will be (1) avitaminoses, with special reference to beriberi, (2) leptospira and yellow fever, (3) helminths, with special reference to ankylostoma, and (4) malaria, blackwater fever, protozoal blood diseases, and kala-azar. The general secretary is Prof. E. P. Snijders of the Institute of Tropical Hygiene, Amsterdam.

Maternity and Child Welfare Conference.

A national conference on maternity and child welfare, organised by the National Association for the Prevention of Infant Mortality, will be held at the City Hall, Cardiff, from July 1st to 3rd. The main subjects of discussion will be a maternity service for the whole nation, the physical and mental health of the normal child of 1–5 years, and children in institutions or boarded-out. Full particulars may be had from the hon. secretary of the association, 117, Piccadilly, London, W.1.

Tavistock-square Clinic.

In connexion with this clinic for functional nervous disorders (51, Tavistock-square, London, W.C. 1) 24 lectures on Psychological Types and Mechanisms will be given on Thursdays from April 30th at the Royal Anthropological Institute, 52, Upper Bedford-place, W.C. Two lectures will be given on each day, the first at 3 P.M. by Dr. Hugh Crichton-Miller, honorary director of the clinic, and the second at 4.30 P.M. by Dr. E. Graham Howe. The course is open only to members of the medical profession. The programme and tickets may be had from the hon. lecture secretary at the clinic.

Royal Institute of Public Health.

The annual congress of this institute will be held at Frankfurt a. M., Germany, from Tuesday, May 19th, to Sunday the 24th (Whitsuntide), under the presidency of Lord Reading. The six sections will be concerned with State medicine and municipal hygiene; architecture, housing and town-planning; industrial hygiene; women and children and the public health; tuberculosis; and pathology, bacteriology and biochemistry. Visits may be paid to centres of interest in and around the city, and to neighbouring spas. The preliminary programme may be had from the hon. secretary at 37, Russell-square, London, W.C.1. Membership of the congress is open to anyone interested.

Legacies to Manchester Hospitals.

At the annual meeting of Ancoats Hospital, Mr. P. M. Oliver, M.P., the treasurer, stated that last year that institution received £20,000 in legacies, and that during the last two years the Manchester hospitals together had received in bequests £335,000. Broadly speaking, 4*s.* 6*d.* in every pound of their incomes came from investments. Mr. Oliver argued that the adoption of sweepstakes would have an unhappy effect upon legacies.

Post-graduate Work at Newcastle.

Post-graduate lectures and demonstrations in medicine surgery, and gynæcology will be given at the Royal Victoria Infirmary, Newcastle-upon-Tyne, from 1.30 to 5.30 P.M. on Thursdays, from April 16th to June 18th. Application should be made not later than April 13th to the Registrar of the College of Medicine at Newcastle.

Cameron Hospital, West Hartlepool.

A children's block, costing between £5000 and £6000, has been added to this hospital. The additions include a ward and veranda with accommodation for 28 beds, and a new all-weather veranda to another ward increasing its accommodation by six beds. Hitherto children have had to be placed in adult wards.

East London Hospital for Children.

The annual report of this hospital at Shadwell, E., states that last year the income fell short of the expenditure by nearly £3000. The ordinary income increased by over £1600, but legacies fell by £670, and although the ordinary expenditure was reduced by £700, a sum of £7850 is owing to the bank. The increase of in-patients treated in the wards exceeded 100, but a dearth of nurses has, it is stated caused a drop in the average number of occupied beds.

Royal Portsmouth Hospital.

The annual report records a steadily increasing demand upon the resources of the hospital, and the surgical staff greatly feel the need of more bed accommodation. Last year there were 3731 in-patients (495 accidents) and 20,700 out-patients, 9456 of whom were casualties. The in-patients stayed an average of 18 days; their average cost was £5 18*s.* 8*d.*, at the rate of £2 6*s.* 1*d.* per week, a slight increase.

Queen's Hospital, Birmingham.

It is announced that unless £3800 is found by this hospital before the end of June, a ward of 24 beds will be closed, the working expenses in 1930 having exceeded the income by £12,000.

Sheffield Royal Infirmary.

Last year the income of this hospital (£60,043) was £11,100 less than the expenditure, and capital expenditure has consequently had to be postponed. It has been suggested that the income of the hospital contributors' association might be increased substantially by obtaining a penny a week from the unemployed of the city and by bringing the "black-coated" workers into the contributory scheme.

Deaconess Hospital, Edinburgh.

Lord Sands, in presenting the thirty-sixth annual report of the Church of Scotland Deaconess Hospital, Edinburgh said that the number treated during the year was 941, an increase of 240 on last year. The major surgical operations were 626, against 373 last year. In the out-patient department there were 7573, as against 6703. This hospital is maintained by the Church of Scotland, as a recognition of the Church's social obligations. Every county in Scotland sends patients. The number of beds is 52.

Motor Insurances and Hospital Costs.

Of the 15,000 casualty and emergency cases treated at Leeds General Infirmary last year, 1205 were accidents attributable to motor vehicles, a slight increase from 192 They cost £4690, an increase of £425. The hope that the Road Traffic Act would give substantial relief in this direction is not being fulfilled, the insurance companies it was stated at the annual meeting, paying to the hospitals only when their insured are shown to be in the wrong.—Victims of road accidents are costing the East Suffolk and Ipswich Hospital about £3000 a year.

Medical Fees at Malton Hospital.

The rules of this institution have been altered to enable payments to be made, in certain cases, to the medical staff. Hitherto any person subscribing 5*s.* per annum was entitled to free hospital treatment, not only for himself, but also for his wife and his children up to 18 years of age. Treatment will still be free to subscribers without dependants whose income is less than £3 a week, and to those with dependants whose incomes are below £4 a week, and other patients may be excused from payment at the discretion of the monthly board. The maximum fee for major operations will be £10 10*s.*, and for minor ones £5 5*s.* Medical cases will pay a maximum of £2 2*s.* a week.

Royal Victoria Infirmary, Newcastle-on-Tyne.

The volume of work last year was greater than at any previous period, the in-patients numbering 15,164. The total number of beds available, including those at the Innes Hopkins Memorial Home, was 576, but the daily average number in occupation was 601. Of the 22,468 accidents treated—an increase of 412—1590 were due to motor traffic; 454 were admitted to the wards, involving a daily occupation of 19 beds. The governors contemplate the provision of further bed accommodation in the main part of the hospital, a complete orthopædic block, a new casualty and reception department, and a new block for the resident medical staff. The cost per occupied bed has been reduced from £160 to £154; the income was £100,257 and the expenditure £93,537. The three wards set aside for paying patients will contain 86 beds.

Financial Position of Liverpool Hospitals.

At the annual meeting of the Merseyside Hospitals Council last week the chairman, Lord Cozens-Hardy, made the disquieting statement that "the financial position of the Merseyside hospitals is still dependent on a continuance of the stream of legacies." Last year the penny-in-the-pound fund contributed £101,000 to the 22 associated voluntary hospitals, but, he explained, that represented only 30 per cent. of their total ordinary income which was £30,000 less than the general fund expenditure, but legacies had reduced the deficit by £25,000. But the £101,000 from the contributory fund covers barely three-quarters of the cost to the hospitals of the contributors and their dependants.—The financial liabilities of the Liverpool Royal Infirmary now amount to nearly £36,000.—The loss on last year's working of the Royal Southern Hospital, Liverpool, was £9515, and at the beginning of the year the hospital owed the bank £10,919, which was reduced by £13,481 by the sale of investments. Proposed extensions have had to be postponed.

Prince Alfred Hospital, Sydney.

In the year ending June 30th, 1930, there were 9550 admissions; 5707 contributed towards the cost of their maintenance to the extent of £10,715. The average stay (530 beds) was 21·31 days. In the out-patient and casualty departments there were 54,241 patients; in the radium clinic there were 5702 attendances. The deep X ray therapy department cannot cope with the volume of work. The hospital has always been the principal clinical school of the University, and it has been felt that the teaching of medicine and surgery, as distinct from the teaching of physiology, anatomy, &c., should be carried out in closer relation to the wards and departments of the hospital. Having this in view, the University of Sydney has received, through the generosity of Mr. G. H. Bosch, the sum of £220,000 for the specific purpose of carrying out the whole of the work of teaching medicine, surgery, and bacteriology in or close to the hospital, and £100,000 has been set aside for the necessary building.

Orthopædic Hospitals.

Plans are being prepared for the rebuilding of the Shropshire Orthopædic Hospital at Baschurch; the existing buildings are of a temporary character. Last year 1413 patients were treated, by whom, or on whose behalf, £41,052 was paid. A large number are received through the agency of public authorities. An offspring of the hospital is the Derwen Cripples' Training College, in grounds adjacent to the hospital, to which patients are sent to be trained in various trades to earn their own livelihood. The work here has so developed that an expenditure of £20,000 to provide additional accommodation is contemplated.—Wingfield Orthopædic Hospital is also to be rebuilt, Sir William Morris having given £17,000 for the purpose. Four of the new wards and the nurses' quarters are expected to be completed this year. In 1930 the patients treated numbered 153 men, 102 women, and 209 children; in addition 95 patients were treated in the private wards. At £22,739 the income exceeded expenditure by £1708.

Glasgow Samaritan Hospital.

At the annual meeting of the Royal Samaritan Hospital for Women, Glasgow, Sir John Stirling Maxwell, the President, recalled that at a similar meeting he had attended in 1890 it was mentioned with satisfaction that 593 in-patients and 508 out-patients had been treated. In 1930 the figures were respectively 3013 and 5078. There had, he said, been a decrease in income, but it was a very small one considering the difficult times.

Glasgow Lock Hospital.

The directors are considering the suitability of some houses on the coast for establishing a convalescent home for children treated at this hospital. Baillie James Dunlop, presiding at the 125th annual meeting recently, said that the financial position was quite satisfactory. He felt very strongly, however, that there was a great need for obtaining compulsory powers to enforce the completion of treatment in defaulters. There was no doubt that efforts in combating venereal diseases were seriously handicapped by inability to ensure a full course of treatment in all cases who reported.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, April 13th.—4.30 P.M., UNITED SERVICES. Annual General Meeting. Election of Officers and Council Paper: Colonel P. H. Henderson: Ambulance Transport in Undeveloped Countries.

TUESDAY.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) 8.30 P.M., PSYCHIATRY. Short Papers. Dr. G. de M. Rudolf: The Experimental Treatment of Schizophrenia. Dr. E. B. Strauss: Some Principles Underlying Prognosis in Schizophrenia.

WEDNESDAY.—5 P.M., HISTORY OF MEDICINE. Paper: Dr. J. D. Rolleston: J. B. Bouillaud (1796–1881): A Pioneer in Cardiology and Neurology. MEDICINE AND NEUROLOGY. Members of these Sections are specially invited to attend the meeting and take part in the subsequent discussion.

THURSDAY.—8.30 P.M., NEUROLOGY. (Cases at 7.45 P.M.) Clinical Meeting at the West End Hospital for Nervous Diseases, Welbeck-street, London, W. Cases will be shown.

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 4.30 P.M.) Cases. Mr. Cecil P. G. Wakeley: 1. Case of Acromegaly. 2. Compressed Fracture of the Lumbar Vertebra. Mr. P. Lockhart-Mummery: 3. Megacolon Treated by Appendicostomy. 4. Carcimona of the Rectum, Seven Years after Operation by Perineal Excision. 5. Colectomy for Multiple Adenomatosis (with Family History). Dr. J. D. Rolleston and Dr. D. G. Macpherson: 6. Tracheotomy in an Adult for Œdematous Laryngitis in Scarlet Fever. Mr. Eric A. Crook: 7. Exophthalmos. Dr. Maurice E. Shaw: 8. Popliteal Aneurysm. Other speakers will take part. 8.30 P.M., ELECTRO-THERAPEUTICS. Short Papers. Dr. J. C. Mottram: Secondary Radiation in Bone. Dr. John Halliwell: Pyelography. Dr. C. A. Robinson: Backache in its Relation to Cervicitis, and its Treatment by Diathermy

HARVEIAN SOCIETY.

THURSDAY, April 16th—4.30 P.M. (at King's College Hospital, Denmark Hill, S.E.). Clinical Meeting.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, April 14th.—9 P.M. (at the Paddington Tuberculosis Dispensary, 20, Talbot-road, W.), Dr. R. S. Walker: The Work of the Tuberculosis Dispensary.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

WEDNESDAY, April 15th.—8 P.M., Mr. D. R. Wilson: Industrial Lighting.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, April 14th.—4 P.M. (in the Rooms of the Medical Society of London, 11, Chandos-street, W.), Dr. C. W. J. Brasher: Absinthe Addiction and the Cocktail Habit.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montague-street, Russell-square, W.C.

FRIDAY, April 17th.—5 P.M., Discussion on the Pre-school Child. Openers: Dr. Ethel Cassie and Dr. G. C. M. McGonigle.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 17th.—4 P.M., Mr. Harold Kisch: Nasal Obstruction.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINIC.

TUESDAY, April 14th.—3.30 P.M. (at the Jessop Hospital), Mr. Chisholm: Heart Disease in Pregnancy and Labour.

FRIDAY.—3.30 P.M. (at the Royal Hospital), Dr. Grout: Radiology in the Investigation of Cardiovascular Disease.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, London, W.

THURSDAY, April 16th.—8.30 P.M., Mr. H. S. Souttar: The Ideal Distribution of Radon Seeds. Mr. W. E. Schall: A Two-valve Transformer. Dr. A. Orliansky: Uniformly Impressed Reduced Prints from Contrasty Negatives. Dr. L. A. Rowden: A Technique of Radiographic Pelvimetry.

FRIDAY.—11 A.M., Visit to North Middlesex Hospital, Edmonton. 5 P.M., Medical Members meeting. Discussion on Uroselectan.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.

WEDNESDAY, April 15th.—4 P.M., Mr. Arthur Gray: Common Causes of Sterility and their Treatment.

ANCOATS HOSPITAL, Manchester.

THURSDAY, April 16th.—11 A.M., Mr. H. Platt: Clinical Demonstration. 4.15 P.M., Mr. E. E. Hughes: Renal Infections.

MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL, Elizabeth-street, Manchester.

WEDNESDAY, April 15th.—4.30 P.M., Dr. J. W. A. Hunter: Leucorrhœa.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 14th.—4.15 P.M., Mr. W. R. Douglas: *Cholelithiasis and Its Complications.*

FRIDAY.—4.15 P.M., Dr. E. B. Leech: Demonstration of Medical Cases.

Appointments

CODY, W. E., L.R.C.P. Lond., M.R.C.S., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Twickenham District of the County of Middlesex.

CURNOW, R. N., M.B., B.S. Lond., Deputy M.O.H. for Derbyshire.

HERBERT S., M.D. Vienna, L.R.C.P. Lond., M.R.C.S., approved by Board of Control under Mental Treatment Act (1930) for Manchester.

Vacancies

For further information refer to the advertisement columns.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.
Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.
Beckenham, Kent, Bethlem Hospital, Monks Orchard, Eden Park. Two Res. H.P.'s. Each at rate of £25 per quarter.
Bedford County Hospital.—H.S. At rate of £175.
Birkenhead General Hospital.—H.P. £100.
Birmingham, Selly Oak Hospital.—Res. Physician. £550.
Blackburn Royal Infirmary.—Fourth H.S. £150.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.
Brighton, Hove, and Preston Dispensary.—District M.O.
Brighton, Royal Sussex County Hospital.—H.P. £150.
Bristol, Brentry Colony for Mental Defectives, Westbury-on-Trym. Res. Med. Supt. £650.
Bristol General Hospital.—Sen. Res. M.O. £200.
Bristol University.—Lectureship in Physiology. £300–£400.
Burnley, Victoria Hospital.—H.P. At rate of £150.
Burton-on-Trent General Infirmary.—Jun. H.S. £150.
Bury Infirmary, Lancs.—H.S. At rate of £200.
Bury St. Edmund's, West Suffolk General Hospital.—H.S. £180.
Carlisle, Cumberland Infirmary.—H.S. to Eye, Ear, Nose, and Throat Dept. At rate of £155.
Chester Royal Infirmary.—H.S. £150.
Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £150.
Doncaster, Royal Infirmary.—H.S. At rate of £175.
Durham County Hospital.—H.S. £150.
Ealing Borough.—Asst. M.O.H. £600.
Gloucester, Gloucestershire Royal Infirmary, &c.—Second H.S. At rate of £120.
Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.S. At rate of £100.
Harrogate Royal Bath Hospital, &c.—H.P. At rate of £150.
Hellingly, East Sussex County Mental Hospital.—Jun. Asst. Res. M.O. £350.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.
Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.
Kingston-upon-Hull, City and County of.—Asst. Tub. Officer. £600.
Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £100.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool and District Hospital for Diseases of the Heart.—Two Research Fellows. £200 and £150 respectively.
Manchester Ear Hospital, Grosvenor-square, All Saints.—Non-Res. H.S. At rate of £150.
Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.
Manchester and Salford Hospital for Skin Diseases.—H.S At rate of £100.
Middlesex C.C.—District M.O. £80. Also Public Vaccinator.
Middlesex Hospital, W.—Anæsthetist. Also Asst. Anæsthetist £100.
Newark General Hospital.—Res. H.S. £175.
Newcastle-upon-Tyne, Royal Victoria Infirmary.—Whole-[illegible] Jun. Surg. Reg. £150.
Northampton General Hospital.—Hon. Surgeon.
Nottingham City Infirmary, Bucknall-road.—M.O. £350.
Nottingham General Hospital.—H.S. and H.P. Each at rate of £150.
Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.
Pembury Institution Hospital.—Res. Asst. M.O. £200.
Poplar Hospital for Accidents, East India Dock-road, E.—Sen. Res. O. £200.
Preston, County Mental Hospital, Whittingham.—Med. Supt. £950.
Public Dispensary, 122, Drury-lane, W.C.—Res. M.O. £150.
Queen's Hospital for Children, Hackney-road., E.—2 H.P.'s. Each at rate of £100.
Rainhill, Lancs, County Mental Hospital.—Visiting Radiologist. £150.
Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.
Redhill, Surrey, Royal Earlswood Institution.—Jun. Asst. M.O At rate of £250.
Rochdale Infirmary and Dispensary.—Senr. H.S. At rate of £250.
Rotherham Hospital.—Cas. H.S. £120. Hon. Surgeon to Ear, Nose and Throat Dept. Also Hon. Dental Surgeon to Out-patients' Depts.
Royal College of Surgeons of England.—Examiners in Anatomy &c. Also Examiners under the Conjoint.
St. Mary's Hospital for Women and Children, Plaistow, E.—Asst. Res. M.O. At rate of £120.
Scarborough Hospital and Dispensary.—Two H.S.'s. Each £175.
Sheffield Royal Hospital.—Ophth. H.S. £120. Also H.P. H.S., and Res. Anæsthetist. Each £80.
Simla, India, Nutrition Research Laboratories.—Chief Researc Worker. Rs. 1500 to Rs. 2500.
Singapore, Straits Settlements, Mental Hospital.—Asst. Med Supt. £700.
South London Hospital for Women, South Side, Clapham Commo S.W.—H.P. At rate of £100.
Southport General Infirmary.—Jun. H.S. £120.
Staffordshire General Infirmary.—H.P. £150.
Swansea General and Eye Hospital.—Cas. O.
University College Hospital Medical School, University-stre W.C.—Beit Memorial Fellowship for Medical Researc £400.
Wallasey Victoria Central Hospital.—Jun. H.S. At rate of £100.
Walsall General Hospital.—H.S. At rate of £150.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Res H.S.'s, and Jun. H.S.'s. At rate of £150 and £100 respectively.
Willesden General Hospital, N.W.—Hon. Clin. Assts. Also H.P At rate of £100.
Wrexham and East Denbighshire War Memorial Hospital.—Res. H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies f Certifying Factory Surgeons at Gnosall (Staffs); Bellshill and Mossend (Lanarks); at Hull (Yorks); an at Thirsk (Yorks).

Births, Marriages, and Deaths

BIRTHS.

BALL.—On March 20th, at "Woodland Croft," Woking, th wife of J. Bramley Ball, L.R.C.P., M.R.C.S., L.D.S. Eng., o a daughter.

HARDIE.—On March 29th, at King-street, Gt. Yarmouth, th wife of Ronald W. W. Hardie, M.B., Ch.B., of a daughter.

MARRIAGES.

JONES—EVANS.—On March 28th, at the Welsh Church, Charin Cross-road, Alan Trevor Jones, M.D., M.R.C.P., of Ca marthen, to Gwyneth Evans, daughter of Mr. and Ms E. Evans, Gunnersbury-avenue, W.

DEATHS.

ANDERSON.—On March 28th, suddenly, at Shanghai, Jo Anderson, M.D., M.R.C.P., D.T.M., of the Henry Lest Institute of Medical Research.

DRAKE.—On March 29th, at Cromwell-road, Canterbur William Drake, M.R.C.S. Eng., L.R.C.P. Lond., former of Taunton and Harwich, aged 59.

REDMAYNE.—On April 1st, at St. Leonards-on-Sea, Thom Redmayne, M.A., M.B., F.R.C.S., aged 67.

STENHOUSE.—On April 4th, at a nursing home, Edinburg Surgeon Rear-Admiral John H. Stenhouse, R.N., retire aged 65 years.

SWAIN.—On March 27th, at Ilford-lane, Ilford, Dr. James Ste Swain (late Major of R.A.M.C., T.F.).

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE QUEST CLINIC FOR CHILDREN.

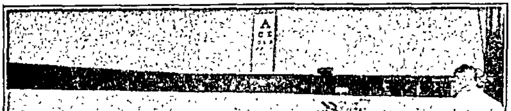
THE "Quest" clinic for children, hitherto situated in Clarendon-road, is continuing its study of nervous and delicate children under very difficult conditions. The clinic is now moving to Robert Browning's house at 19, Warwick-crescent, W.2. It has already achieved interesting results in spite of restricted accommodation, inadequate income, and a great increase in the number of applications for admission. The annual report for the year 1929–30 states that 54 children were treated and that the actual clinical work had to be curtailed in order to organise the office and a system of records. Each child is seen first by a physician, who gives it a complete physical examination and records progress at monthly re-examinations. Children with definite organic disease are referred to the proper authorities; those with mild lesions continue to attend the clinic while receiving treatment elsewhere, whereas those in whom no organic disease is found remain under the sole care of the clinic. There is a small pathological department. It is stated that metabolic urinary studies have been made on most of the cases, but that it has been impossible to develop the laboratory to the extent desired. The work in the psychological department has followed the lines of previous years, involving many kinds of approach by which the child can give expression to its conscious and unconscious phantasies. The methods have proved effective in three cases of epilepsy. The work of the social department has been heavy, and a worker has been lent by the Child Guidance Clinic. Every attempt is made to see the child's adaptation to life from as many angles as possible and conferences are held on all cases that do not appear to be simple. The rhythm department has detected two definite types of response, and the exercises are said to have benefited the children considerably. Every worker with children knows how much the fate of the neurotic child depends upon the parents; psychotherapeutic treatment is available for mothers and fathers at this clinic with much benefit to the whole family. A special course has been initiated to train men and women in the principles of modern dynamic psychology and remedial work. It is hoped in the future to be able to provide much more room and equipment and to develop the biochemical and record work; it is believed that valuable psychological laws are buried in the case-sheets.

AN INDUSTRIAL CLINIC.

Messrs. R. A. Lister and Co., Ltd., of Dursley, Glos., have just opened, close to their engineering works, a clinic equipped with medical and dental apparatus, and have arranged with three local doctors and two local dentists for one of each to be in attendance daily. It is not intended to compete in any way with the panel service, but it is hoped that the presence of doctors and dentists in the factory will lead to the firm's employees applying for treatment at the moment it is needed and thus avoiding dangerous delays. Incidentally by preventing avoidable ill-health the clinic should increase the efficiency of the staff of 1500 men. The scheme is the outcome of a meeting between the directors and representatives of the employees, which considered the large amount of time lost from illness or injury owing to the distance of employees' homes from the works, with consequent delay in seeking medical advice.

The medical clinic here illustrated is open during working hours, and one of the three doctors in the town attends every day from 12.30 to 1.30, or later, according to the number of patients. The attendant is an ex-chief petty officer, sick bay attendant, who deals with dressings and dispenses such things as cough mixtures. One of the directors gives examples of the way in which the clinic is reducing sickness and loss of time. A burnt arm is dressed by the attendant during the dinner hour and again before the man goes home; a visit to his doctor would have entailed temporary absence from work and the drawing of sick benefit. Two or three cases of measles recently occurred in one department of the works; every man working in this department was examined in the clinic with a view of checking a spread of infection. A man in the foundry was found to have diphtheria and swabs were taken in the clinic from the throats of the other men.

At the dental clinic two local dentists attend on alternate days, excepting Saturdays, during the luncheon hour. Their charges to members of approved societies are in accordance with the rules; to non-members slightly less than the charges made at their private surgeries, since the firm supplies equipment. Increasing numbers are visiting the clinic.



An industrial clinic.

SOCIOLOGICAL DATA FROM BIRTH CONTROL CLINICS.

A VERY thorough and painstaking examination has been made by a non-medical author of the sociological data furnished by 70,000 cases appearing in the records of 70 birth control clinics in Germany, Austria, Russia, Great Britain, and the United States.[1] The bibliography extends over 20 pages. The medical reader will find in the book no information on the comparative value of different contraceptive methods, and he will derive from it no guidance on how best to advise the patients who consult him on this subject. Hence the book will be of less interest to the practitioner than to the medical officer of health, for whom the question now arises of providing what are called "birth control facilities."

Of the sociological findings arising out of the actual clinic statistics, perhaps the most interesting is that in the United States these clinics are apparently used as freely by Roman Catholics as by persons of other religious persuasions. Thus, according to the U.S. Census of 1920 and the Catholic official Year Book of the same year, 30 per cent. of the population of New York, Chicago, Newark N.J., and Cleveland, Ohio, were Catholics. The statistics of the birth control clinics that have been working in these cities between 1921 and 1928 show that 36 per cent. of their clientèle are Catholics.

---

[1] Seventy Birth Control Clinics. By Caroline Hadley Robinson. Baltimore: Williams and Wilkins Company. 1930. Pp. 351.

The general argument of the book is to the effect that birth control is not to be regarded as in any strict sense a *cause* of that fall of the birth-rate which has occurred so conspicuously in all civilised countries in the last 60 years. It is to be regarded rather as the means by which a wish has expressed itself. The *wish* to have fewer children is the essential cause of the decline in fertility above referred to, and according to the author is generated by some means (not as yet understood) by the numerical increase of population and by the consequent overcrowding which has thus arisen. That the actual practice of contraception cannot be regarded as in the proper sense causal is strongly suggested by the position in Ireland, wherein contraception is little used. That country by the extensive use of celibacy and emigration "keeps her birth-rate at the moment the lowest in all Europe, except Esthonia." Mrs. Robinson advances elaborate and well-reasoned arguments for supposing that the qualitative effects upon the population of the work of birth control clinics is not as harmful as is often alleged. This conclusion is put forward despite the unanimous opinion, fully appreciated by the author, of practically all competent British authorities that the existing birth control methods are impracticable by those classes whose fertility is likely to be the most prejudicial to society. It is possible that in this connexion conditions in England may differ from those obtaining in the United States. There are reasons for supposing that the class designated in the recent report of the Mental Deficiency Committee as "The Social Problem Group" does not exist in the United States as it does in England. Failure to distinguish, among the large proportion of unskilled labourers' wives who attend the clinics, between the wife of a bona fide worker and the wife of a more or less unemployable social parasite may have obscured an important issue. The wives of the latter are, in fact, little represented at the English clinics. This distinction is difficult to establish statistically; yet it is of the first importance in evaluating the social effects of present-day birth control.

THE USE OF STATISTICS IN MEDICINE.

DOCTOR and actuary regard life from different aspects. The actuary seeks to find out a probability factor from his experience of a great number of lives in bulk; the doctor is primarily concerned with the individual's expectation of life and the means of improving it. Nevertheless, as Mr. F. L. Collins showed at a meeting of the Medico-Legal Society recently, mortality statistics are indirectly of incalculable value to the medical profession. One of the most important factors in the awakening of the national conscience in the middle of the last century to the importance of human life and the possibility of its prolongation by improved sanitation and environment was, as Mr. Collins pointed out, the pioneer work of Farr. He was the first man in this country to apply census returns and death registers scientifically to the betterment of the public health, and the Public Health Acts, which were passed in the 'seventies, were due in large measure to the light which he shed. Mortality statistics are of ever-increasing importance to medical officers of the public service as a guide to the efficacy of their health administration, and they form the foundation of national health insurance and Government pensions schemes. To those who desire to appreciate more fully the importance of mortality tables to the life of a community Mr. Collins recommended a study of the Registrar-General's Decennial Supplement. It may be that actuarial technique will remain to the practitioner of medicine something of the mystery which the language of the pathological laboratory is to the actuary. But this does not justify the rejection of mortality tables on the ground that "statistics can prove anything." Honesty and competence ensure that statistics shall be used only as ins for discovering truths, and every fair-minded m man will grant to the actuary a measure of t qualities equal to that which he claims for himself.

INDUSTRIAL HEALTH EDUCATION.

SOME folk make a brave show with but little outside the shop front; others with an inferiority complex make but little show with much worth exhibiting. The annual report of the Industrial Health Education Society belongs to the latter category; it is laconic rather than precise. Anyone who has been present at some of the talks organised by the society knows the good work it is doing. Perhaps it may be a group of 50 to 150 coal-miners collected in a welfare hall to listen to a lecture on nystagmus, and thereafter to heckle the lecturer; or a number of tinplate workers in a village institute gathered to discuss their occupational troubles; or some cotton operatives eager to hear about spinners' cancer. The human touch is present at these meetings, bringing the scientist in contact with the object of his research; and he is learning as well as h audience the value of knowledge. Well may t society choose as its annual motto the words sp on its behalf by the Prince of Wales: "No man's work should be a danger to his health or a menace to his life." There is much room for propaganda to teach those who want to be taught how to earn a healthy life in the industries of the country. This is the work of the society, and we hope it will continue to expand.

THE ROLEX "PRINCE" WATCH.

THE Rolex "Prince" watch has been designe to introduce a new and useful feature in wrist watche The face has two dials, the upper one showing th hours and minutes, and the lower one the second The seconds dial, which is 9 mm. in diameter, can b read clearly, with all the convenience implied fo clinical purposes. One winding keeps the movemen going for 58 hours, and a compensating hair-sprin protects against irregularities of temperatures, i which connexion the firm possess a certificate o excellence by the Swiss Government Observatio Station. The watch is not unduly large, bein slightly curved fits comfortably to the wrist, and i appearance is an attractive piece of jewellery. Th price ranges from 8 guineas to 40 guineas, and th name of the nearest agent for its supply can b obtained from the Rolex Watch Co., Ltd., 40/4 Holborn Viaduct, E.C.1.

A USEFUL SAINT.

To the Editor of THE LANCET.

SIR,—I had recently occasion to investigate th exact meaning of the French word "acariâtre" (crabbed; cross-grained; waspish, &c.), and consulted the latest edition of Larousse's excellen dictionary. For the first time I see that it gives th etymology, as follows: "de Saint Acaire, qu guérissait les fous." I have consulted several histori of saints, and other large French and English encyclopædias, but cannot discover any account or even th name of the saint. As a saint who cured mad peop would have certainly an interest for medical historians perhaps one of your learned readers would help.

I am, Sir, yours faithfully,

London, April 8th, 1931. ETYMOLOGIST.

SOUTHAMPTON HOSPITALS' ASSOCIATION.—The second annual report of the Southampton and District Hospitals' Association shows that in 1930 the receipts more than doubled, and that 45,000 cards have been issued for the current year. The working expenses have been reduced from 14 to 6 per cent.

ADDRESSES AND ORIGINAL ARTICLES

QUININE THERAPY IN MALARIA.*

BY PHILIP MANSON-BAHR, D.S.O., M.D. CAMB.,
F.R.C.P. LOND.,

PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES; LECTURER
AT THE LONDON SCHOOL OF HYGIENE AND
TROPICAL MEDICINE.

THERE is nothing more perplexing to the average student of tropical medicine than the varied and often totally contradictory ideas regarding the exhibition of quinine in malaria. For the last 300 years physicians of all nations have agreed that quinine in some form or other is specific for malaria fever, and since the discovery of the plasmodium it has been generally conceded that it exerts a parasitotropic effect upon the parasites of that disease. In fact the action of quinine upon malaria is cited in most text-books as a classical example of the specific and highly specialised drug action upon a particular parasite. But all physicians are by no means agreed upon the principles and methods of its practical application. There have been periods, as, for instance, during the war, when heroic and massive doses of quinine were given with the idea of extirpating *in toto* the plasmodium from the human body, whilst neglecting, or even disregarding, its subsequent deleterious effects upon the organism as a whole. After the armistice saner ideas again prevailed, since it has been realised that the main objects of annihilation have not been obtained by heroic dosage, and since it is held by some that massive quinine therapy does not only not prevent relapses but may actually predispose towards them.

VARYING RESISTANCE OF PARASITES.

When considering quinine therapy in malaria it is necessary to bear in mind that there are three species of malaria parasites, causing three clinically distinct diseases. These parasites also differ one from another in their amenability to quinine. The benign tertian and the subtertian are the most generally distributed and therefore the most frequently encountered in general practice, while the quartan is by far the most infrequent as a cause of illness and disability. It may be stated in general terms that the subtertian fevers re the most amenable to quinine therapy and that he benign tertian and quartan are much more efractory. By this statement is meant that, though the more pressing symptoms disappear when quinine is absorbed into the blood stream, yet a residuum of parasites escape or are rendered refractory to the drug and form the nucleus from which relapses may arise, often at long intervals after the primary attack. therefore propose to discuss this matter further from my personal experience in the practical treatment of malaria rather than particularly to review the experience of others.

First I would state my belief that, as in other protozoal infections in man, the primary attack is more susceptible to treatment than are relapses. This means to say that it is possible to extirpate the infection in the human body by the energetic, prompt, and timely exhibition of quinine, but that in each subsequent relapse the parasites are more resistant to the drug as they become more accustomed to its presence. Every tropical physician can point to individual cases of malaria in which a *therapia magna sterilisans* appears to have been brought about by quinine.

There is one other point—a very important one—which is often lost sight of, and that is the resistance of the human body to infection. In addition to specific therapy every other adjuvant must be enlisted to augment the *vis medicatrix*. This is the underlying factor in the apparent failure of quinine therapy, especially in benign tertian infections in a debilitating tropical climate where the body resistance is lowered by constant exposure to heat and, it may be, to superadded tropical infections. We are all familiar with the virulence which malarial infections assume in times of war, national stress, and famine. The removal of a patient from a hot steamy atmosphere to a temperate and dry climate not only increases the bodily resistance of the patient and renders him less liable to serious manifestations, thereby making quinine treatment more effective, but it also very materially shortens the life of the parasite in the human body. It has been sufficiently proved in recent years that the different malaria parasites have a limited life-span in the human body; they cannot live a limitless existence, as is popularly supposed. The life of a benign tertian infection in a temperate climate is probably one of three years, that of the quartan perhaps even longer, whilst that of the subtertian is by far the shortest of the three, and is probably under one year from the time of primary infection. So great a factor is this effect of climate that some benign tertian infections in Europeans in the tropics appear to be totally refractory to quinine.

Methods of Administration.

The salts of quinine which are commonly used in practice are: the sulphate, soluble in 800 parts of water; the hydrochloride, soluble in 40 parts; the bihydrochloride, soluble in 1 part; and the bisulphate, soluble in 11. Another salt-quinine, the ethylcarbonate, containing 81 per cent. of the alkaloid, has the advantage of being practically tasteless—an important factor in the case of ladies and children. It has the advantage of being readily absorbed, whilst other so-called tasteless preparations, such as the tannate and carbonate, are practically useless on account of their insolubility. The hydrochloride is generally regarded as the most useful preparation for general use, whilst the more soluble bihydrochloride is held in reserve for intramuscular and intravenous medication.

The most favourable moment to administer quinine during the actual attack of malaria has been the subject of speculation. It is no longer regarded as dangerous to exhibit quinine when there is a degree of pyrexia, but it is, I think, generally agreed that the drug exerts its maximum effect if given when the acute paroxysm is declining and when the patient is beginning to perspire, for at that moment the parasites have sporulated and the merozoites are free in the blood-plasma and in a condition in which they are most susceptible to the action of quinine.

Many methods have been advocated to mask or remove the bitter taste of quinine. An agreeable and efficacious method is to prescribe it in an effervescing mixture with citric acid grs. 10, to which are added grs. 4 of ammonium carbonate and grs. 20

---

* Lecture delivered at a meeting held at the Wellcome Historical Medical Museum, London, in celebration of the three hundredth anniversary of the first recognised use of quinine by Europeans.

of potassium bicarbonate. Quinine is rendered less bitter if dissolved in milk, whilst syrup of orange and glycerin disguise the taste, and a practical method of cleansing the mouth is to chew a piece of bread.

Occasionally, when given in large doses, quinine may produce deafness and amblyopia, which may prove very persistent and occasionally permanent. The amblyopia is due to spasm of the arterioles of the retina and the deafness to the direct action of quinine upon the auditory nerve. Quinine idiosyncrasy or quinine intolerance is occasionally met with, and may be a most disturbing factor. In some people even minute doses of quinine may produce a profuse and most irritating urticaria, in others intractable dyspepsia, whilst in others, again, a rare, but genuine, quinine hæmoglobinuria has been noted. A useful method of determining quinine idiosyncrasy has been described by Dawson and Garbaile, who have shown that if a solution of 1 : 10 quinine is applied to a scratch on the forearm a zone of œdema and erythema immediately appears in a susceptible person.

Benign Tertian Malaria.

The most dramatic results of quinine therapy are seen in this form of malaria; so striking are the cutting-short of the fever and the disappearance of the parasites from the blood stream that the effect of quinine upon the temperature curve is often used as a method of differential diagnosis from other fevers, in the absence of a microscopical examination. Whatever the exact explanation may be, it has been established as a scientific fact that quinine has a selective action for the trophozoites of this infection and a much less marked action upon the sexual forms. This phenomenon is much more striking in subtertian infections.

A benign tertian malaria attack is usually ushered in with a rigor and a high temperature. Vomiting is not usually a special feature, so that quinine may be readily exhibited by the mouth. Directly the patient commences to perspire the first dose should be administered, and to promote sweating it is advantageous to combine it with grs. 10 of aspirin. For an adult male European the optimum daily dosage, as laid down originally by Manson (a rule which is followed at the present day), is grs. 30 divided into three doses of grs. 10 each. There appears to be no special advantage in giving larger doses than this, but I have frequently observed that smaller doses, such as grs. 15 daily, do not control the fever nor cause the parasites to disappear from the circulation. The maximum dosage should be kept up for four days and then dropped to grs. 20 daily for the next week. I am convinced that the generally held belief that it is only necessary to exhibit quinine for a short period after the fever attack is a great mistake and actually predisposes towards further relapse, so that it is necessary to institute an anti-relapse treatment. Personally I favour the method of giving grs. 10 daily for six weeks after the more massive treatment described. Others, I know, favour the week-end treatment, which consists of grs. 15 daily for three days in the week. The underlying principle is to extirpate the last remaining malaria germ in the system by daily bombardments with quinine. Unfortunately this desideratum is by no means always obtained.

Smaller doses of quinine are given to women, the maximum being grs. 20 a day, whilst children tolerate the drug well; one-twentieth of the adult dose should be given for each year of age, so that a child of 5 years would receive one-quarter of the adult dose.

It is to be regretted that even by continuous qu therapy the prevention of subsequent relapses be absolutely guaranteed; as James has shown, th may occur from nine months to one year after th apparent cure of the infection. To avoid this disagreeable possibility the resistance of the body should b built up by good food, fresh air, and moderate exercise. There is some reason to suppose that salvarsan ha some action on the parasite in the quiescent stage or at least exerts a definite tonic action on the bod I am therefore in the habit of giving one or injections of neosalvarsan 0·3 g. as an adjuvant to quinine therapy. Iron and arsenic tonics are frequently given with the quinine. Of one thing I am certain, and that is that quinine does not exert its maximum effect unless the intestinal tract is in a receptive state for its absorption. Therefore it necessary to combine quinine therapy with a aperient such as Epsom salts, which should be give at the commencement of quinine and subsequent once or twice weekly.

Although intravenous and intramuscular quinine injections may on occasions be useful in comb especially virulent benign tertian infections, yet is no evidence to show that the course of the is necessarily shortened thereby. I am convin that only small doses of quinine are indicated malarial cachexia; it is much more advisable to gi suitable arsenical tonics and iron injections than t resort to continuous drenching with quinine.

Subtertian Infections.

Subtertian malaria infections may run a very course or may be extremely severe. The para differs from that of benign tertian mainly in rapidity with which it multiplies and in its mode reproduction by sporulation in the smaller cap which by these means may be completely blo with masses of parasites and blood stasis may produced. It is a curious fact that the trophozoi are extremely susceptible to the action of even in small doses, while the sexual forms, crescents, are extremely resistant. Thus it is com paratively easy to control the more urgent signs an symptoms with relatively small doses of quinine, y when the patient is recovering and the fever quiescent, crescents may be found in numbers in th blood stream and may persist for several weeks. fact it is extremely difficult to extirpate the with quinine. I have records of cases in whi crescents persisted in the blood for 28 days af grs. 840 of quinine had been absorbed. When th is no persistent vomiting or other contra-indicati quinine should be given by the mouth in subt malaria. It is not necessary to give such large d as in benign tertian; the dosage should commen with grs. 15 of the alkaloid in solution and gradua increase to the maximum of grs. 30 daily. But very severe toxic cases in which there has been considerable degree of blood destruction with co sequent anæmia, great caution has to be observ in "pushing" quinine on account of the liability blackwater fever; the dosage should therefore beg with grs. 5 daily and gradually increase.

In the more severe clinical forms with bilio vomiting, and maybe with delirium, quinine giv by the mouth does not suffice to control sympto and resort must be had to intramuscular injecti which in such circumstances appear to act like charm. The bihydrochloride salt should be use The whole rationale of intramuscular quinine has bee much discussed. It is unquestionable that whe ever or wherever quinine comes into contact wi muscle-fibre it causes a degree of necrosis, so that the dosage of quinine must be carefully gauged and the site of injection selected. The proper dosage for quinine injection is about grs. 10 and the site of injection the gluteus maximus muscle. I am very averse to multiple quinine injections and daily injections, and I cannot see that they are therapeutically indicated. I consider three or four injections weekly ample. *It is hardly necessary to state* that quinine injections, especially if given into a limited area and at frequent intervals, are not without danger. They may produce profuse necrosis and even (in the absence of any specific microbic infection) profuse suppuration and tetanus. I have seen cases uncontrolled by blood examination (and they should invariably be so controlled) treated by continued injections in the belief that they were controlling fever, when all the time the rigors were brought about, not as had been supposed by a particularly resistant parasite, but by the continued absorption of pus from minute intramuscular abscesses.

Intravenous injections of quinine are indicated in the so-called pernicious forms of subtertian malaria, especially when the sporulating parasites are congregated in the capillaries of the brain, producing coma, or in the coats of the intestines producing choleraic diarrhœa or other forms of abdominal disease. The rapidity with which intravenous quinine acts in these dramatic states is remarkable. The bihydrochloride salt should be used, in a dosage of grs. 10 in 10 c.cm. of distilled water, injected into the median basilic vein. There is no indication for more heroic doses than this, as larger quantities are very apt to bring about too great a dissolution of the parasites and dangerous symptoms may ensue. It is much safer to give smaller injections of quinine—grs. 3 each—at frequent intervals. As it has been shown that intravenous injections of quinine are apt to be followed *by a fall of blood pressure, it is advisable to combine* it with the injection of ♏ 5 of a 1 : 1000 solution of adrenalin.

Quinine by enema has been advocated, especially for treating subtertian infections in children. It is given in grs. 10 doses, using milk or starch (4 oz. with 3 drops of tincture of opium) as a menstruum, but there is no evidence that much of the drug is absorbed.

Subtertian infections are more easily cured by quinine than are benign tertian, so that it is not necessary to give such a prolonged course of anti-relapse treatment, and I am convinced that often in this disease the desideratum of *therapia magna* is attained. However, in general the main scheme of quinine therapy *should* be followed.

Blackwater Fever.

Does quinine produce this catastrophe or predispose towards it, or does it *not*? I confess I find it more difficult than ever to answer this question. To my mind it is unquestionable that blackwater fever is an accident which occurs only in subtertian infections *and not in the other two forms of malaria. In many* cases I have noted that the exhibition of massive doses of quinine (by this I mean grs. 20–30) does certainly seem to precipitate the attack, and I have *learnt to be especially suspicious of those cases of* subtertian malaria who are obviously ill, whose spleens are greatly enlarged, but in whose blood relatively few parasites are to be found. It may be *that quinine is but one of the factors that predispose* towards the blackwater state—there may be others, such as cold, alcohol, or the toxins of some other disease—or it may be that quinine in certain individuals brings about in the red corpuscles a state of greater susceptibility to hæmolysis. At any rate it must be borne in mind that the rôle of quinine in the production of blackwater fever is very widely believed. Suspicious cases *of subtertian infection* should therefore be treated with great circumspection, graduated quinine dosage being combined with alkalis and with a liberal supply of glucose.

Quartan Malaria.

In quartan malaria large doses should be used and the maximum dose of grs. 30 should be persisted in longer than in benign tertian, as quartan parasites are much more resistant to the action of quinine than the other two, and parasites can be demonstrated in the blood for ten or more days after the initiation of quinine therapy. The question of anti-relapse treatment is also important, as quartan is by far the most persistent infection and relapses may occur over as long a period as five years. The tendency of quartan infections to be associated with nephritis should also be noted, and it has been shown that the appearance of albumin in the urine in this infection is an indication *for pushing the quinine dosage.*

The Newer Compounds.

In attempting to synthesise quinine in the laboratory Schulemann, Schönhofer, and Wingler some seven years ago produced a derivative of quinoline which is now known as plasmoquine. The probable action of this compound on malaria in man was gauged by its comparative action upon the plasmodium of birds (canaries artificially infected). Roehl and Hörlein were the better enabled to do so as it had already been shown by Sergent and Giemsa that quinine acted upon the plasmodium in the birds' blood in the same way as it did upon the human malaria parasites. Plasmoquine, in doses of 0·06 g. (gr. 1) daily, caused *a rapid* disappearance of benign tertian parasites from the blood of man, but had a lesser effect upon the ring forms of the subtertian parasite. Most remarkable, however, is its marked selective action upon the *sexual forms*. The *benign sporonts disappear* almost immediately, whilst the otherwise refractory crescents disappear in about four days after a total of 0·24 g. of the drug, so that in plasmoquine a new malaria specific has undoubtedly been discovered. But there are cogent defects in the drug. The doses originally advocated—0·25 g. and 0·12 g.—were obviously far too large and were often accompanied by alarming toxic symptoms, such as a livid blue cyanosis of the lips and nails, which is due to the conversion of hæmoglobin into methæmoglobin. Moreover, its inability to control subtertian fever was disappointing.

It was then demonstrated by Schulemann and Memmi that not only was the therapeutic action of plasmoquine greatly enhanced but its toxic manifestations were greatly diminished, or rather neutralised, by the addition of a small amount of quinine. Hence the composition of plasmoquine compound. Each *modern tablet of plasmoquine* compound contains 0·01 g. (gr. 1/6) of plasmoquine with 0·125 g. (grs. 2) of quinine sulphate. The scheme of dosage is to give the drug in full doses of six tablets daily for one week (*i.e.*, *plasmoquine gr.* 1 and quinine grs. 12 daily) with three days' interval between each weekly course for five separate weeks, as an anti-relapse treatment. I believe that plasmoquine compound is *a useful adjuvant to quinine treatment and in many* circumstances an efficient substitute. It is easy to take, and is comparatively tasteless. Many people can tolerate it who are intolerant of quinine in ordinary therapeutic doses. It is in my opinion more efficacious in controlling benign tertian malaria than is pure quinine; it frequently cures an infection which appears resistant to pure quinine. It banishes the crescents from the blood in subtertian malaria. In appropriate doses it is readily taken and readily absorbed by children and it is readily borne by pregnant women, in whom it controls the fever while it does not predispose to abortion, as does pure quinine. I have had several cases of intractable malaria in pregnant women who have gone to full term on plasmoquine therapy without any further attacks. Manifestly plasmoquine has attained a distinct place in our armamentarium against malaria, and it has opened up vistas by the exploration of which less toxic and even more specific antimalaria drugs may be obtained.

ACUTE DISSEMINATED ENCEPHALOMYELITIS:

ITS SEQUELÆ AND ITS RELATIONSHIP TO DISSEMINATED SCLEROSIS.

BY DOUGLAS McALPINE, M.D. GLASG.,
M.R.C.P. LOND.,

PHYSICIAN IN CHARGE OF DEPARTMENT FOR NERVOUS DISEASES, MIDDLESEX HOSPITAL; PHYSICIAN TO HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE.

THIS paper is based upon a small number of cases of acute disseminated encephalomyelitis which have been observed for varying periods after the acute attack, and from these and a study of cases described in the literature certain conclusions have been arrived at regarding the association between acute disseminated encephalomyelitis and disseminated sclerosis. It is hoped that these may serve the purpose of drawing attention to this problem which, on the clinical side, presents many difficulties.

A Review.

Although scattered references to acute disseminated encephalomyelitis are to be found in papers for some years past, it is only within the last six years that the condition has attracted much attention. On the clinical side three groups of cases have occurred: (1) post-vaccinal; (2) following infectious fevers; (3) spontaneous.

Post-vaccinal.—In 1912 the histological changes of post-vaccinal encephalomyelitis were recognised, for the first time, by Turnbull in a single case. In 1926 Turnbull and McIntosh[15] reported seven cases showing the same association, in each of which a pathological examination was made. In every case the vaccination was a primary one, and symptoms of encephalomyelitis showed themselves from 7 to 12 days after the vaccination. Drowsiness, headache, and vomiting were common at the onset; there was pyrexia varying from 102° F. to 105° F. Two cases showed strabismus and three Kernig's sign, and an extensor response was present in two cases. Death occurred between the fourteenth and fifteenth days after vaccination and was preceded by increasing coma and incontinence of urine and fæces and, in some cases, by abolition of the deep reflexes. The authors mention that complete recovery was the rule in the cases which survived.

Between the years 1924 and 1928 150 cases of post-vaccinal encephalitis were reported from Holland. At first the condition was considered to be epidem encephalitis and it was thought that the dis had been lit up by the vaccination, but subsequentl this view was generally abandoned, chiefly because th incidence of encephalitis was steadily dim during the years 1926 and 1927, at a time when pos vaccinal encephalitis was reaching its zenith. In t cases the clinical picture was similar to that seen England, as exemplified in Turnbull and McIntosh paper. In adults headache, fever, and paralysis the extremities, with sphincter disturbances, exten plantar responses and, as a rule, depression of th deep reflexes, were not uncommon. The mortali in the Dutch and English cases varied betwe 25 per cent. and 50 per cent. In those who s recovery was usually rapid and remarkably compl

Following Infectious Fevers.—Of the inf fevers measles seems to be the commonest of encephalomyelitis; varicella and mumps precede it. Greenfield,[4] in a recent paper, descri four cases following measles, two of which were fat The following is a résumé of one of these cases was under the care of Dr. Gordon Holmes.

A girl, aged 6, showed a measles rash on March 7th, 1 On March 31st she appeared drowsy and was seized w generalised convulsions which occurred at regular intervals there were, also, other attacks characterised by clo movements involving the right side of the body. La on in the same day she became semi-stuporose and Che Stokes respirations were noted. On April 1st she was drowsy; a flaccid paresis of the limbs on the right side noted as well as incontinence. There were no signs. On the same day the temperature rose, the movements became generalised, and she died.

Another case showed a similar picture, whilst another meningeal signs were prominent. In following case recovery took place.

A female, aged 24, under the care of Dr. James C was taken ill with measles on May 25th, 1928. On June she had retention of urine and during the next 24 h gradually lost all feeling in the legs as high as the becoming completely paralysed. No voluntary mi or defæcation were possible; she showed a complete flac paraplegia. The upper abdominal reflexes were but the lower were absent; apart from a diminution vibration sense in the legs, sensation was normal. The reflexes in the lower limbs were absent; the p responses were flexor. The cerebro-spinal fluid showed material change from normal. By June 15th she h greatly improved and was able to stand and walk feebl the deep reflexes had now returned. She subsequen appeared to make a complete recovery.

Wohlwill[16] has described two cases.

In the first a child aged 4, on the fourth day after appearance of a measles rash, became stuporose and sho myoclonic movements of the upper limbs with a fla paresis of the lower limbs, diminished reflexes, and a positi Babinski's sign. The temperature was 105° F. T cerebro-spinal fluid contained 400 cells per c.mm. Th days later the child became comatose, and it died following day.

In a second case, a child of 4, the symptoms were v similar but meningeal signs were present.

Further references to cases in the literature may found in Greenfield's paper.

Greenfield refers to the cases in which the spi cord is chiefly involved: "The paralysis, which usually flaccid, tends to become spastic after the fi few days with increase of the deep reflexes and extensor type of plantar response; here, too, t recovery is remarkably complete. . . This picture temporary paraplegia with loss of sphincter cont and incomplete or dissociated anæsthesia is characteristic of the myelitis following measles th the few cases in which the paralysis has been of anoth type may be discounted." A review of the cas reported in the literature bears out this observation.

Greenfield [6] has also published two fatal cases of encephalomyelitis following "influenza."

In the first case broncho-pneumonia was present from the onset. The second was as follows: a male, aged 32, was taken ill on Feb. 3rd, 1928, with headache and indigestion; the temperature was 100° F. On Feb. 4th he had severe frontal and occipital pain. Two days later, on attempting to move his legs, he found himself paralysed; he also had retention of urine and burnt his foot on a hot-water bottle. On Feb. 13th the cranial nerves and upper limbs were normal; there was a flaccid paralysis of the lower limbs with loss of thermal and pain sensibility up to the level of Poupart's ligament; vibration, postural sensibility, and touch were normal. The knee- and ankle-jerks were absent; plantar responses could not be obtained. The cerebro-spinal fluid showed 17 cells per c.mm. and 0·06 per cent. of protein; the Wassermann reaction was negative. On Feb. 16th he developed a cystitis; the knee-jerks were now feebly present and sensation began to return two days later. On Feb. 25th he died of pyelitis and bed-sores.

Histologically both these cases proved to be typical disseminated encephalomyelitis. There seems little reason to associate the word "influenza" with the second case which, from the clinical description, appears to have been one of spontaneous encephalomyelitis.

Spontaneous Encephalomyelitis.—In 1927 Redlich [12] published an account of 12 cases which he had observed between 1924 and 1927. Three-quarters of the cases were in persons under the age of 30. The onset in every case was between the months of January and June and was usually sudden. Fever was present in four cases, and absent in four, and in the remaining four cases no mention was made of this symptom. Pain was a prominent feature in about half the cases; it was referred to the trunk and limbs and was sharp and shooting. Paresis in the lower limbs, varying in degree, developed within the first two or three days, except in a few cases in which its appearance was delayed for a week or so. In nearly every case some temporary paresis of sphincter control was noted. Nystagmus and varying degrees of ataxia were present in approximately half the cases; a single or double extensor response was noted in all but two cases. Sensory disturbances in the lower limbs and on the trunk occurred in about half the cases; in three of these the loss was more marked on, or confined to, the lower limb and the corresponding side of the trunk. Redlich lays emphasis on this tendency to a Brown-Séquard syndrome. In only one case were signs of meningitis found. Diplopia was rare; facial paresis occurred in one case and the relative escape of the cranial nerves was noteworthy. In seven cases no fresh symptoms or signs developed after the first three weeks. In the remainder relapses occurred at intervals of some months. In approximately half the cases residual signs such as nystagmus and extensor responses remained.

Redlich believed that these cases, many of which resemble acute disseminated sclerosis, can be distinguished from this disease on the following grounds: (1) Cerebral signs in acute disseminated sclerosis are more pronounced than in his cases, and retrobulbar neuritis, which is common in disseminated sclerosis, did not occur in a single case. (2) Although, perhaps, a Brown-Séquard syndrome may be met with in disseminated sclerosis, in his experience it occurs in the later stages of the disease and not in the acute phase, as in his cases. (3) Relapses in acute disseminated encephalomyelitis are exceptional.

Three cases occurred in persons over the age of 40, and in each of them the posterolateral regions of the cord were affected. Redlich alludes to the resemblance of these cases to funicular myelitis associated with pernicious anæmia; he states that none of them showed any signs of pernicious anæmia, but no details of the blood and gastric findings are given. Two of his cases were as follows:—

CASE 1.—A female, aged 16, was seized, during the middle of March, 1924, with sudden sharp pains round the waist. Two days later numbness and tingling appeared in the feet and stiffness in the legs. Three days later pains were felt in the legs and she had retention of urine. The temperature was *slightly raised. On March 27th the* cranial nerves were normal. There was a slight tremor of the upper limbs on voluntary movement. A marked degree of spastic paraplegia was present, with double extensor plantar responses. There was anæsthesia to all forms of sensation below the tenth dorsal segment. The cerebro-spinal fluid was negative. By April 7th active movements had begun to return in the legs and the anæsthesia was less marked. Later, bladder control returned, as did the power in the left leg. There remained a moderate degree of paresis of the right leg. Sensation returned, except for a strip of anæsthesia between the tenth and twelfth dorsal segments; a slight tremor of the right hand was still present. The abdominal reflexes returned later. In February, 1927, she walked well and was able to climb hills, but the plantar responses remained extensor. No fresh signs were noted.

CASE 7.—A boy, aged 11, was taken ill in September, 1925, with a sore-throat followed by weakness in the legs on getting up from bed. After a few weeks he complained of pains in his legs and his writing became uncertain. Walking improved, but early in 1926 it became worse again. In June, 1926, there was no nystagmus and the optic discs were normal. Speech was slightly nasal. There was slight ataxia on the finger-nose test, but no intention tremor; both lower limbs were moderately paretic and the gait was ataxic. The plantar responses were extensor; there was no pes cavus. Sensation was intact. The cerebro-spinal fluid showed a negative Wassermann reaction, one cell per c.mm., and a normal colloidal gold curve. He was discharged from hospital in October, 1926, when the signs were still present.

Flatau,[3] in 1929, described 17 cases observed in Poland during the year 1928 which showed disseminated lesions of the central nervous system. The onset was sudden; the initial symptoms were pains and various paræsthesiæ such as a pins-and-needles sensation or a sense of constriction, accompanied or soon followed by weakness in the limbs and often by a mild fever. In one case there were dysphagia and dysarthria. The seventh cranial nerve was involved in several cases and vision was affected in a few, usually bilaterally. Incontinence of urine was a frequent and early symptom. There was little or no disturbance of sleep. In some cases there was weakness of all the limbs, but more usually a varying degree of paraplegia, though sometimes the paresis assumed a hemiplegic distribution. In a few instances muscular atrophy appeared. In about three-quarters of the cases there were signs of pyramidal tract involvement. In one case only were the deep reflexes in the lower limbs abolished. Objective sensory loss was rare, thermal sensibility being diminished below the waist in one case and in another on one arm. Two cases proved fatal; the remainder rapidly improved. No information is given as to the subsequent findings. No mention is made of nystagmus or ataxia in the clinical description of the cases.

Brain and Hunter,[2] under the title "Acute Meningo-encephalomyelitis of Childhood," described six cases in which the most striking features were: (1) the age varied from 3 to 18 years; (2) all the patients developed their symptoms between April 16th and May 28th, 1928; (3) the onset was acute and fever was present in each case, ranging from 99·4° F. to 105° F.; (4) meningeal symptoms were present in all but one case. In two cases meningitis constituted the only neurological sign, but in the remainder evidence either of involvement of the cerebrum, such as hemiplegia and aphasia, or of the spinal cord, such as weakness in the lower limbs, was present in addition. One case showed trismus; this has been noted in some of the post-vaccinal cases. One case proved fatal; the remaining cases, despite the severity of their condition, recovered completely in a comparatively short time. In every case the cerebro-spinal fluid was normal.

Martin,[7] in reporting four cases observed in London during 1928, laid emphasis on the fact that in each case the symptoms suggested a widespread infection of the central nervous system. They came on in a series of attacks, different parts of the cerebro-spinal axis becoming affected suddenly at different times. Two of his cases died, one made a complete, and the fourth a partial recovery.

Spiller[13] has recently reported two cases of which the second may be cited.

> A man, aged 34, on Oct. 6th, 1924, complained of numbness in the feet which in four days had ascended as high as the hips. During the night of Oct. 11th he experienced severe pains on the right side of the chest and later at the same level on the left side. The spinal fluid showed an increase in the cell count. By Nov. 10th paræsthesiæ were felt in the right hand and right side of the face. Walking caused fatigue; there was no fever. Dysphonia and dysphagia developed; there was no diplopia. The patient came under observation on Nov. 20th, 1924. Speech was nasal and the soft palate was paralysed bilaterally; thermal sensation was impaired on the left side of the face. Nystagmus was present on looking to the right. The abdominal reflexes were absent. Pain and thermal sensibility were greatly impaired in the left upper and lower limbs and left side of the trunk. The limbs were not paralysed but tired easily on exertion; both plantar responses were flexor. The patient was too ill for more careful examination and died two days later. The histological examination showed changes fairly typical of acute disseminated encephalomyelitis.

Strauss and Rabiner[14] described under the title "myeloradiculitis" six cases which from their description seem to have been cases of acute disseminated encephalomyelitis. Pains in the trunk and limbs, followed by a rapid onset of flaccid paraplegia in the lower limbs with absent deep reflexes, segmental sensory loss (chiefly thermal), and sphincter disturbance were the commonest findings. In all there was rapid recovery.

Further papers dealing with the same subject have been published by Pette,[11] Montzka,[8] and others.

PATHOLOGY.

A survey of the pathological findings in the fatal cases, whether occurring after vaccination (Turnbull and McIntosh, Perdrau[10]) after infectious fevers (Greenfield), or spontaneously, leads to the conclusion that the histological picture is essentially the same in all. It may be summarised as follows.

1. The lesions are disseminated, being found in both brain and spinal cord. In the majority of cases the white and grey matter are about equally affected.

2. The essential lesion consists of a perivascular zone of demyelination, which may be discrete or of considerable size.

3. Perivascular cellular infiltration varies greatly in its intensity; in a few cases it has been absent. In many cases there is a broad zone of cells outside the adventitia which extends for some distance into the surrounding tissue, quite unlike the closely packed "cuff" so characteristic of epidemic encephalitis. Lymphocytes, plasmacytoid, microglial and endothelial cells may be present. The pons, medulla, and lumbar regions of the cord are specially attacked (Turnbull and McIntosh, Perdrau); this again helps to differentiate the disease from epidemic encephalitis, in which the site of predilection is th mid-brain. Greenfield, in commenting on the histological appearances in two cases of "influenzal encephalomyelitis, states: "The similarity of th lesion in these two cases to those of encephalomyelit which follows vaccination and small-pox is remarkab close." He might also have added measles, as own work shows. "Slight differences may be f in the type of cellular reaction in the lesion, but th must of necessity vary according to the length the period between the onset of the lesion and death. Perdrau comes to the same conclusion.

SUMMARY OF CLINICAL PICTURE.

The disease sets in abruptly in an otherwise h person. Fever is often present and is particularl marked in children; in adults it may be a throughout. In children headache and meninge signs are common. Highly characteristic of disease is the manner in which fresh ne symptoms appear, usually within the first three wee but in rare instances up till some few months fro the onset. Another and striking feature is th rapid recovery which takes place even in case which have shown evidence of severe involvemen of the central nervous system; this recovery i usually complete, but in some instances cert sequelæ may remain. The mortality is low in th spontaneous cases but higher in those which follo vaccination and the infectious fevers.

It would be possible to classify the various of encephalomyelitis according to the part of neuraxis mainly affected. However, the dissemi nature of the pathological process might be lost sig of and no good purpose would serve such classifica It is obvious, however, from the reported cases the main incidence of the disease may fall on cerebrum or spinal cord.

In the *cerebral* type, which perhaps occurs m frequently in children, meningeal symptoms an signs are frequent and may constitute the who clinical picture. Convulsions are general and may occur at the onset and during the acute phase stupor amounting to coma has been frequently Focal signs, such as hemiplegia, hemianopia, aphasia, have been often observed. In fatal coma becomes increasingly deep. Recovery may complete, but in a few cases hemiplegic signs m remain.

In the *spinal* type pain is an early and s feature. In some cases the pains may be to one part of the trunk; frequently they are m generalised. They are described as sharp or sho and are extremely severe; they may last some ho or days. Other forms of paræsthesiæ are comm such as numbness or a pins-and-needles sensation, a sense of constriction, usually in the limbs or low trunk.

Motor weakness in the lower limbs which rapidly progress to a complete loss of power is usua noticed within a day or two of the onset, but in oth cases not until the end of two or three weeks. Th paresis may be accompanied by an increase of d reflexes in the lower limbs with an extensor plant response. In other cases all the deep reflexes ma be absent with an extensor or equivocal plant response. In one of my cases the knee-jerks wer abolished while the ankle-jerks were exaggerated both plantar responses were extensor. Distur of sensation probably occur in about half the case There may be a diminution of all forms below certain level; more usually the lower limbs affected unequally and certain forms of sensation are impaired more than others. This particularly applies to heat, cold, and pain sensibility (see personal Case No. 1). Sphincter disturbance, from a slight difficulty in starting micturition to complete retention, is nearly constant and is usually an early sign.

To this purely spinal cord picture may be added signs indicating implication of the brain stem. The commonest of these are nystagmus and ataxia in the upper limbs. I have noticed that the nystagmus in this disease is extremely rapid and fine, but as I have seen so few cases I do not wish to dogmatise on this point, although, if confirmed by others, it might serve as a useful differential point between this disease and disseminated sclerosis, in which the nystagmus is less rapid. A unilateral or bilateral ataxia may occur, usually most marked in the upper limbs. Redlich, in his original paper, remarks on the comparative escape of the cranial nerves in this disease, and in the main the reports of others seems to bear this out. Particularly striking is the escape of the upper cranial nerves; *diplopia is extremely rare.* The optic nerve, which, as Paton[8] has recently reminded us, is a tract of white matter in the central nervous system and therefore subject to the same pathological changes that occur in the white matter elsewhere, is rarely affected and then, as a rule, bilaterally, resulting in a sudden fall of vision. In such cases the diagnosis of neuromyelitis optica, a disease characterised by bilateral diminution of vision and signs of a myelitis and which has been considered by some to be a separate disease from disseminated sclerosis, is likely to be made. A facial palsy has been reported in some cases, as also have bulbar symptoms such as dysphagia and dysphonia.

Changes in the cerebro-spinal fluid are infrequent. In the cases showing meningeal signs there may be no cellular increase; in other cases a moderate increase in the lymphocyte count may be found. The Lange gold curve is not mentioned in many reports; on the whole no change has been noted.

Sequelæ.

I have not met with any article dealing with the sequelæ of acute disseminated encephalomyelitis. The following four cases show sequelæ of varying severity.

CASE 1.—A female, aged 14, was admitted to the Hospital for Epilepsy and Paralysis, Maida Vale, on Dec. 22nd, 1927. On the morning of Dec. 6th she had had two teeth extracted under *novocain. The same afternoon* she suddenly "felt shaky all over" and could not walk straight; she "staggered all the way home." On the next day the right arm, right side of the trunk, and right leg felt numb and a few hours later she noticed weakness in the right hand and right leg, especially in the latter. On Dec. 8th the numbness disappeared from the right arm but remained in the right leg for several days. She was unable to walk owing to weakness in the right leg. On Dec. 15th the left leg and left side of the abdomen became numb, but the power in this leg *remained normal.*

On admission to hospital there was no obvious euphoria. The pupils were equal and reacted normally. A very fine, rapid nystagmus was present on looking to either side. The discs were normal, as were the remaining cranial nerves. There was a slight paresis of the right upper limb, especially distally, and the deep reflexes on this side were exaggerated; no sensory loss could be detected. None of the abdominal reflexes could be obtained. A marked degree of weakness of the right foot was present; the movements at the right knee-joint were slightly less affected. The right knee-jerk was brisker than the left; there was right ankle-clonus. The power of the left leg was good. The right plantar response was extensor, the left flexor. Sensation was diminished on the left leg and left side of the trunk up to the level of the seventh dorsal segment; pin-prick, thermal and pain sensibility were chiefly affected, cotton-wool and vibration sense to a lesser extent. At a later date, tactile sensation became normal. In the cerebro-spinal fluid the Wassermann reaction was negative, the total protein was 0·025 per cent., and the cells 1–3 per c.mm. The Lange gold curve was normal.

The condition gradually improved, but on her discharge on March 18th, 1928, there was still considerable weakness of the right foot, especially of dorsiflexion, and slight weakness *of the right hand. The sensory loss remained as before.*

On April 8th, 1929, no fresh symptoms had developed; fine rapid nystagmus was still present; the left leg still dragged on walking and there was no further appreciable return of power; no weakness of the right arm could be detected. The abdominal reflexes were still absent. Pain and thermal sensibility remained definitely diminished below the seventh dorsal segment on the left side; vibration sense was equal on the two sides and other forms of sensation were unaffected.

On Oct. 3rd, 1930, the patient stated that she had been perfectly well except for the weakness of the right leg. Fine nystagmus and a Brown-Séquard syndrome remained as before. In the cerebro-spinal fluid the Wassermann reaction was negative, the cells numbered 2–3 per c.mm., the protein was 0·03 per cent., and the Lange gold curve was normal.

CASE 2.—A male, aged 22, on Oct. 9th, 1928 "felt off colour" *and alternatively "hot and cold"* with *pains in* his limbs. The same afternoon he vomited. He went to bed and remained there until Oct. 21st. Shortly after getting up, he had acute pains of the girdle type round the waist and his legs became so weak that he fell. He had considerable difficulty in passing urine. The vision in the right eye became blurred. On the following day he again vomited, but the pains abated somewhat. Dr. E. R. Lovell, of Billericay, noted that there was nystagmus, absent knee-jerks on either side, and a doubtful extensor plantar response. *On Oct. 24th there was a recurrence of girdle pains, with* pain also at the back of the neck. On Oct. 28th the pain radiated down the right arm. Thereafter he slowly improved. He was admitted to hospital on Nov. 29th. He no longer complained of pain but felt weak and unsteady when walking.

Examination showed no obvious euphoria. Pupils were equal and regular in outline and reacted normally. A rapid, very fine horizontal nystagmus was present on lateral fixation of the eyes. There was no pallor of the discs. Articulation was normal. There was a slight paresis of the right arm with definite ataxia on the finger-nose test. Apart from a slight degree of postural defect in the fingers of the right hand, sensation was normal in the upper limbs. The deep reflexes were present and equal in the two arms. The abdominal reflexes were absent. There was a moderate degree of paresis of the lower limbs, more especially of the right, with a mild degree of hypertonus. The right knee-jerk was absent; the left was feebly present. Both *ankle-jerks were exaggerated and a double extensor plantar* response was easily obtained. Vibration sense was diminished in both legs below the iliac crest; there was a slight loss of postural sensibility in the toes; sensation was otherwise normal. Ataxia was marked and was mainly of the cerebellar type; there was no disturbance of sphincter control. In the cerebro-spinal fluid the Wassermann reaction was negative, the cells numbered 1–3 per c.mm., the total protein was 0·03 per cent., and the Lange gold curve was normal.

When discharged from hospital on *Feb. 5th, 1929,* power had improved in the lower limbs and the gait was much less ataxic. The right knee-jerk was just obtainable. The other signs remained as before. He has remained under observation and no fresh symptoms or signs have appeared. He was re-examined on Sept. 25th, 1930. Fine nystagmus and bilateral extensor responses were still present but the power in the legs was now nearly normal. The abdominal reflexes had returned and were now brisk. The knee-jerks were more active than when he left hospital in February, 1929 but were still definitely less brisk than the ankle-jerks. The cerebro-spinal fluid contained 1–3 cells per c.mm., and the percentage of protein was 0·025. The Lange gold curve was normal.

CASE 3.—A female, aged 25, was seized whilst at work at 2 P.M. on June 20th, 1928, with a severe pain which shot through the right knee and then radiated upwards towards the right groin and then downwards towards the foot. The pain was intermittent, shooting in character, and of great severity. *One hour later* a similar pain followed by a "pins-and-needles sensation" was felt in the left leg. At about 5 P.M. numbness was felt in the feet and spread quickly upwards to just above the groins, and at the same time the legs became weak. She did not micturate for about 18 hours and then had no sensation of the act. By the end of 48 hours the numb feeling had passed off, but the pains were severe for another two days. She remained in bed until the fifth day of the illness, but on getting up found that her legs were still weak.

She was admitted to the National Hospital, Queen-square, on July 17th. I am indebted to Dr. I. M. Allen, registrar to the hospital, for a note on her condition on admission: "Positive findings. Fine nystagmus to right and left. Some weakness of dorsiflexion of right foot. Pin-prick diminished right leg, especially in distribution of third, fourth, and fifth lumbar segments. Vibration sense diminished right leg. Right knee-jerk absent. Left plantar response not obtained. Abdominal reflexes very active; other tendon reflexes normal. The cerebro-spinal fluid contained one cell per c.mm., 0·045 per cent. of total protein, and no excess of globulin; the Lange test showed no change. The Wassermann reaction was negative in the cerebro-spinal fluid and blood. On July 25th both plantar responses were extensor. On July 30th the right knee-jerk was obtained and the plantar responses were indefinitely flexor. On August 20th both plantar responses were flexor but the right knee-jerk was still less than the left. On August 31st the patient was discharged with considerable improvement in motor power subjectively and objectively. Some sensory loss remained in the right leg and the right knee-jerk was still diminished."

The patient was admitted to the neurological ward of the Middlesex Hospital on August 18th, 1930. She stated that after leaving hospital in 1928 the power in the legs continued to improve but that the right leg tired easily after walking a short distance, and that at times she felt a pain in the right knee; otherwise she had been free from symptoms. On examination there appeared to be no euphoria. A rapid fine horizontal nystagmus was present on lateral fixation of the eyes to the right and left. The discs were normal. There was no weakness, tremor, or ataxia in the upper limbs. Dorsiflexion of the right foot was slightly less good than that of the left; otherwise the power of the lower limbs was good. There was no muscular wasting. The abdominal reflexes were active and equal on the two sides. The left knee-jerk was brisk and the right diminished; both ankle-jerks were active and equal and the plantar responses were flexor. There was no loss of tactile sensation on the lower limbs, but slight diminution of thermal sensibility over lumbar segments 3–5 on the right side without any appreciable loss to pin-prick. Vibration sense was slightly diminished on the right leg as compared with the left. The gait appeared normal. The cerebro-spinal fluid showed a normal Lange gold curve and no abnormality was observed.

CASE 4.—A male, aged 29, was seized one day during the third week in March, 1929 with severe pains in both lower limbs. He had to walk a distance of half a mile to his home, during which time the pains occurred three or four times. They were so severe that he thought he would faint, and were shooting in character. On reaching home he went to bed. The pains continued and spread to the back; he also had a severe headache. He remained in bed four days. On getting up he found that his legs were weak; he could just manage to walk round his room. He had no trouble with micturition. On the ninth day he returned to work but was still unable to walk properly, although he could drive his car. Two days later he noticed numbness around the knees, which spread to the ankles; this sensation disappeared at the end of a few days and a fortnight later his legs were practically well again. At the beginning of August he went on holiday; three or four days later he was seized with severe pains in his legs and again they became weak so that he had difficulty in walking. Thereafter he gradually improved, but a slight weakness of the left leg remained. At no time had he any trouble with his vision.

When seen at the Middlesex Hospital on May 3rd, 1930, he complained of fatigue in the left leg after walking about half a mile. Examination showed no euphoria or nystagmus, and normal pupillary reactions. The discs were well coloured. There was no paresis, sensory loss or ataxia in the upper limbs. The abdominal reflexes were diminished on the left side. A slight degree of motor weakness was present in the left leg, with brisker reflexes and an equivocal plantar response on this side; the right was definitely flexor. Apart from diminished vibration sense below the level of the iliac crests on either side, no sensory loss was found. When re-examined on Oct. 8th, 1930, he stated that he was able to drive his car about 80 miles a day, but was still troubled with weakness and occasional aching pains in his legs after walking a short distance. No change in the physical signs was noted except that the left plantar response was flexor, though not as definitely as the right. The cerebro-spinal fluid showed the Wassermann reaction negative, three cells per c.mm., 0·03 per cent. of protein and a normal Lange gold curve.

The diagnosis of acute disseminated encephalomyelitis seems extremely probable in each of thes cases. The rapid occurrence of a Brown syndrome in Case 1, the intense pains in the remai three cases and the abolition of deep reflexes in C 2 and 3 are points of diagnostic importance. Th sequelæ are severe in the first two cases and neglig in the remaining two. In Case 1 a Brown- syndrome remains. Case 2 now presents a pictur indistinguishable from chronic disseminated sclerosis the knee-jerks, which were absent at the outset, ha now returned. The only point which would no help to distinguish this case from one of disseminate sclerosis is the fact that the abdominal reflexes ar present despite a double extensor plantar response. Had the disease been disseminated sclerosis, th abdominal reflexes would almost certainly have bee absent. In Case 3 a retrospective diagnosis was made, based on the history and findings whilst sh was an in-patient in the National Hospital and her present condition. In this case and in Case importance was attributed to the pains at the onset which in each case were of great severity. In Case the diagnosis might be contested because of relapse three months after the onset; however, of Redlich's cases showed fresh signs after a simil period. Cases 3 and 4 show few remaining signs the symptoms consist of a certain amount of pain i the legs with undue fatigability.

Muscular atrophy is mentioned in the literatur as an occasional sequel. I have seen one such case 14 months after the acute illness, in which th diagnosis of acute disseminated encephalomyeliti was probable but, as I have been unable to obtain reliable history, either from the patient herself or he doctor, I have thought it best to omit the case.

In the cerebral type a complete recovery is not t be anticipated in every case, therefore a hemiplegi or aphasia may be expected to remain, but I myse have encountered no such case. The diagnosis i the initial stages, when the symptoms and signs ar confined to the cerebrum, is likely to be epidemi encephalitis, polio-encephalitis, or meningitis. I must be recognised, however, that fresh cases o epidemic encephalitis have been exceedingly during the past four years and that poliomyeli usually occurs only in the autumn months. It probable, therefore, that many cases of acute di seminated encephalomyelitis, particularly of th cerebral form, have been mis-labelled during th past four years and that in consequence the nature of their sequelæ has not been recognised.

Relationship to Disseminated Sclerosis.

This is a difficult question and one which it impossible to answer with our present knowled especially of the bacteriology of the two diseas However, it is of interest to consider the prob from a clinical and pathological standpoint.

Marie [6] was the first to draw attention to the clo relationship that may exist between the infectio fevers and disseminated sclerosis. He particular referred to typhoid fever, small-pox, scarlet fever, an measles. Since the occurrence of disseminat encephalomyelitis in almost epidemic form duri the past few years, sometimes as a sequel of vaccin tion and measles, there has been considerable con troversy on this point. Redlich's views have alread been cited and his reasons given for separating th two conditions. Pette, on the other hand, think that the various forms of encephalomyelitis, whic have become more frequent since the war, should be regarded as an expression of a new disease, but rather as bearing a close relationship to disseminated sclerosis. He believes that it is impossible to separate encephalomyelitis and multiple sclerosis, either from the symptoms or the pathological findings. He thought that when sclerosis was really present, multiple sclerosis could be considered as the causal condition; in other words, a diagnosis of multiple sclerosis can only be made when sufficient time has elapsed for sclerosis to form. This view-point is open to considerable criticism. Presumably those cases of acute disseminated encephalomyelitis which do not clinically recover, and ultimately die, will show sclerotic patches indistinguishable from those found in true disseminated sclerosis. A study of the type of cellular reaction in the acute stages of both conditions would be more likely to throw light on this question. Perdrau, as the result of a comparison of the histological picture in post-vaccinal encephalomyelitis and disseminated sclerosis, comes to the conclusion that the perivascular demyelination in each is essentially similar and, apparently on this finding, discussed the possibility that the agent responsible for the demyelination in these two diseases as well as in the other forms of disseminated encephalomyelitis may be the same for all of them.

This possibility might be considered, but there is another disease characterised by demyelination which, by our present standards of knowledge, has no relation to either disseminated encephalomyelitis or disseminated sclerosis—namely, encephalitis periaxialis diffusa (Schilder's disease).

Brain,[1] in a recent critical review of disseminated sclerosis, records a case which was under the care of Dr. W. Langdon Brown and which illustrated these difficulties.

A girl, aged 4, had an acute illness characterised by drowsiness, ataxia, and spastic weakness of the limbs. She made a good recovery but relapsed two years later with similar symptoms. In addition, visual impairment occurred in this attack. She again recovered, but the same symptoms returned 18 months later. She then showed bilateral primary optic atrophy, nystagmus, bilateral pyramidal signs, and slight ataxia, most marked in the left upper limb.

Brain remarks that in the acuteness of onset and severity of general symptoms this case resembled acute disseminated encephalomyelitis; in clinical features it recalled neuromyelitis optica, and in its relapsing character disseminated sclerosis. "In the face of this and similar cases, it is difficult to maintain a rigid distinction between the three groups." Disseminated sclerosis is unknown at this age; this would appear to be an exceptional case of disseminated encephalomyelitis in which immunity did not follow the first attack.

My personal belief, which is without any valid proof, is that acute disseminated encephalomyelitis and disseminated sclerosis are caused by a different virus, though they may present a very similar picture. The close resemblance between them will be apparent from the following case.

A spinster, aged 21, was seen in consultation on Dec. 17th, 1927, with Dr. C. D. Pye-Smith, of Huddersfield, to whom I am much indebted for detailed notes on her case.

On Oct. 14th, 1927, whilst at a dance, she was seized with intense giddiness followed by vomiting, which persisted for 24 hours. There was no pyrexia. On Oct. 20th there was recurrence of vomiting and blurred vision, with a "funny feeling" in the right foot. On Nov. 1st she had a tingling sensation in the left hand; ataxia was now marked, with difficulty in standing, and slight paresis of the right external rectus. The temperature was 99·0° F. On Nov. 20th she showed great improvement; there was no diplopia or nystagmus, and the gait was normal. On Dec. 4th there was tingling of the left hand and foot. On Dec. 5th she had a recurrence of acute vomiting with stiffness of the left side of the neck; the temperature was *normal*. On Dec. 6th there was violent oscillatory nystagmus in both eyes, but no diplopia. Vomiting continued; in the evening "pins-and-needles" sensation was felt in the left arm, trunk and leg, and the left side of *the face and she had* slight difficulty in starting micturition: the plantar responses were still flexor. On Dec. 17th I noted the following points. There was no obvious euphoria, but marked rotatory nystagmus on lateral fixation of the eyes and diplopia on looking to the right. The fundi were normal; there was no paresis of the limbs and no sensory loss, but marked cerebellar ataxia in all *four limbs, especially* on the left side, and an extremely ataxic gait. The abdominal reflexes were absent; the deep reflexes exaggerated *but equal; the left* plantar response was feebly flexor, the right definitely flexor. There was no disturbance of sphincters; lumbar puncture was not performed.

The diagnosis in this case between disseminated sclerosis and acute disseminated encephalomyelitis would have been difficult except for one incident in the past history which turned the scale definitely in favour of disseminated sclerosis. In September, 1926, whilst on holiday at the seaside, the patient had a very transient attack of numbness on the right side of the body and vomited several times. These symptoms lasted *about four days, and this* attack, at the time, was ascribed to sun-stroke. Subsequently she was re-examined on March 12th, 1928. Nystagmus, absent abdominal reflexes, a slight intention tremor and a less definite flexor response on the left side were the only abnormal signs. The patient remained perfectly well, playing games, &c., until June, 1930, when she complained of pain and numbness in the left forearm and the right thigh, tingling in the fingers and a tight sensation round the body in the region of the iliac crests, with a feeling of heaviness in the legs on walking. Dr. Pye-Smith, in addition to the above signs, found that the left plantar response was now definitely extensor. Since then the symptoms have again disappeared.

Differential Diagnosis from Acute Disseminated Sclerosis.

In the acute stage.—The following points may be of help in distinguishing between these two conditions in the acute stages.

1. A temperature of over 100° F. is in favour of acute disseminated encephalomyelitis.

2. Severe shooting pains rarely occur in acute disseminated sclerosis but are common in acute disseminated encephalomyelitis.

3. Diplopia, common in acute disseminated sclerosis, is rare in acute disseminated encephalomyelitis; in the latter condition nystagmus, when present, is finer and more rapid than that seen in disseminated sclerosis. Retrobulbar neuritis may occur in both conditions but is more frequent in disseminated sclerosis, when it is usually unilateral; in acute disseminated encephalomyelitis both eyes are generally affected.

4. Euphoria, which is common in early disseminated sclerosis, is rarely, if ever, met with in disseminated encephalomyelitis.

5. Sensory loss in disseminated sclerosis, when present, commonly involves postural and vibration sense: in acute disseminated encephalomyelitis thermal and, to a lesser extent, pain sensibility may be affected.

6. Loss of the deep reflexes in the lower limbs is not uncommon in acute disseminated encephalomyelitis, but is of rare occurrence in disseminated sclerosis.

The chronic stage.—The sequelæ of acute disseminated encephalomyelitis, especially in its spinal form, may resemble a chronic case of disseminated sclerosis closely, as exemplified in Case 2. If this case had not been seen in the acute stage when the deep reflexes were absent, a diagnosis of disseminated sclerosis would almost certainly have been made. The differential diagnosis must therefore in many cases rest on the history of the acute illness. The points previously mentioned may be of some help in a doubtful case. Should a relapse occur some months after the onset, then the case should be classified as one of disseminated sclerosis and treated accordingly; in others, if no satisfactory history can be obtained, it may be impossible on clinical grounds to distinguish between the two diseases; repeated examination of the cerebro-spinal fluid may afford some help. The Lange gold curve is positive in about 50 per cent. of cases of disseminated sclerosis. A repeatedly negative Lange curve in a case showing signs suggestive of disseminated sclerosis, and in which no fresh signs or symptoms have developed since the onset, would not exclude this disease, but would render the diagnosis doubtful. In such a case energetic arsenical treatment is not indicated, and the possibility that the case might be a sequel to acute disseminated encephalomyelitis should be borne in mind. Persistence of abdominal reflexes in the presence of extensor plantar responses, diminished deep reflexes, thermal sensory loss, absence of euphoria, presence of muscular wasting and a negative cerebro-spinal fluid are findings which, especially if more than one be noted in a case, should raise a doubt as to the diagnosis of disseminated sclerosis. In such a case every effort should be made to obtain an accurate history of the onset and, if possible, of the signs present at that time.

In the four personal cases mentioned in this paper no fresh signs or symptoms have been noticed since the onset, but as they have been under observation for a comparatively short time little importance can be attached to this, in view of the fact that remissions in disseminated sclerosis may last several years. Of perhaps more importance is the fact that the cerebro-spinal fluid has remained normal in all four cases. A case of Dr. G. Riddoch's mentioned by Turnbull and McIntosh is of interest in this connexion.

A girl of 21 was vaccinated on May 25th, 1921. On the twelfth day she felt ill and had retention of urine, shivering, and a temperature of 102° F. On the fourteenth day she was unable to stand or walk, had lost sensation completely below the waist on the seventeenth day, began to recover sensation and voluntary movement on the twenty-first day, but had slight spastic paresis of the lower limbs when admitted to hospital on the thirty-fourth day after vaccination. Five years later there was still defective sensibility to pain, heat, and cold in and below the ninth thoracic segment, and incontinence of urine and fæces in cold weather, or when the patient was tired.

Dr. Riddoch has kindly informed me that when he examined the patient again in April, 1930, he found that she had made an almost perfect recovery. Sensation was normal, as was control of the bladder, except when she was worried. In this case, which has been observed over a period of nine years, no fresh symptoms or signs have appeared.

Conclusions.

Within the last few years a form of acute disseminated encephalomyelitis has occurred, in 1928 in epidemic form, in this and other countries, either spontaneously or following vaccination or infectious fevers. On clinical and pathological grounds it is believed that these cases, whether occurring spontaneously or otherwise, may be due to the same virus. The final proof of this can, however, only be provided by bacteriology. The mortality is low. Except in rare instances in which relapses may occur during the first few months the acute phase generally does not exceed two or three weeks. Sequelæ may result, and may be extremely varied in their clinical aspects. In such cases the recognition of the original cause, unless the case is seen in the acute stages, may be a matter of great difficulty. A retrospective diagnosis in such a case may be possible if a careful history be obtained of the initial symptoms, particularly as to the presence of pain. Disseminated encephalomyelitis, both in its acute phase and in its sequelæ, may closely resemble disseminated sclerosis. It is suggested, but without any proof, that a different virus is responsible for these two diseases, and that in acute disseminated encephalomyelitis immunity is usually conferred upon the person by the first attack, whereby relapses are prevented.

THE INCIDENCE AND SOURCE OF BRUCELLA ABORTUS INFECTION IN MAN.

BY ROBERT CRUICKSHANK, M.D. ABERD.,
LECTURER IN BACTERIOLOGY TO THE UNIVERSITY; BACTERIOLOGIST TO THE ROYAL INFIRMARY, GLASGOW;

AND

W. J. BARBOUR, M.D. GLASG.,
ASSISTANT MEDICAL OFFICER AND PATHOLOGIST, GARTLOCH MENTAL HOSPITAL, GARTCOSH.

Kristensen, commenting in 1928 on the high incidence of *Brucella abortus* infection among the population of Denmark, stated: "There is no reason to believe that this infection is more widespread here in Denmark than in other countries where cattle-breeding is carried on to the same extent; it must be supposed that if systematic enquiries of a similar nature were set on foot in Germany and England the same conditions would be found." So far, however, there has been no evidence to suggest that human infection with *Br. abortus* is so widespread in Britain as it is in Denmark, where 500 cases were discovered in 13 months by the agglutination test (Kristensen and Holm) or in the United States of America where, according to a recent report, there were 206 cases in 1927, 635 in 1928, and 402 from January to May, 1929 (Hardy). Since 1925, less than 30 cases of "abortus fever" in man have been reported in Britain, and yet contagious abortion of cattle is probably as common here as in the two countries mentioned. The suggestion that the low incidence of the infection is more apparent than real, and is to be ascribed to a lack of clinical consciousness of the disease, gains some support from the discovery of five cases of "abortus fever" in Glasgow during the past nine months (see Cruickshank and Cruickshank) and from the fact that Harrison and Wilson (1928) in Manchester examined 998 sera submitted for Wassermann reaction and found that 50 (5 per cent.) agglutinated *Br. abortus* in dilutions varying from 1 : 10 to 1 : 80.

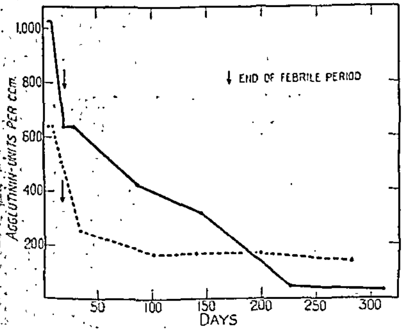
To find out if there existed any undiscovered incidence of *Br. abortus* infection in and around Glasgow, two samples of the population were chosen: (*a*) the in-patients of a general hospital; and (*b*) a community in close association with aborting cows. The criterion of infection, past or present, was the presence in the blood-serum of agglutinins to *Br. abortus*. A high concentration of agglutinins in the presence of undulant fever may be regarded as diagnostic of active "abortus fever"; the identification of past infection depends on the persistence of agglutinins in the blood after an attack and requires the establishment of a diagnostic titre.

Br. abortus infection of bovine origin may be derived either directly from the cow by contact with infected discharges or indirectly by drinking infected milk. It was hoped, by examination of the two samples of the population, to discover which was the more common source of infection. Further, the milks from all the cows in an infected herd were bacteriologically tested by guinea-pig inoculation, so that information about the excretion of *Br. abortus* in the milk might be obtained. As a large number of the cows, both infected and healthy, had recently received an injection of living but attenuated *Br. abortus* vaccine, the effect on these animals of abortus inoculation could be studied.

Agglutination after Abortus Fever.

It is generally agreed that during an attack of undulant fever agglutinins to the infecting organism may be present in great concentration, no other organisms giving such a high agglutination titre as is given at times by brucella (see Dalrymple-Champneys); for example, in three cases examined by one of us the titres were 1 : 2500, 1 : 1600, and 1 : 3200. If these agglutinins persisted in the blood for a prolonged period after infection, and were evoked by infection only, retrospective diagnosis of undulant fever could readily be made and an estimate of the incidence of past infection in a group of individuals could be obtained. There are, however, few records about the persistence of agglutinins in the blood after an attack of abortus fever; Kristensen and Holm have recently given data which indicate that the specific agglutinins disappear within a few months to a year after recovery from the disease.

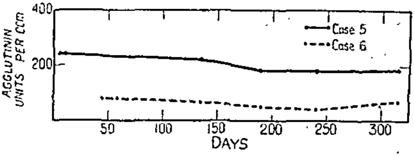
FIG. 1.



Agglutinin content of the serum in two cases (J.M. and M.K.) of "abortus fever." Continuous line = J.M., dotted line = M.K.

In the present investigation, the sera of two cases of abortus fever (J.M. and M.K.) have been examined for agglutinin content over a period of ten months, while similar records have been kept of two farm-workers whose sera agglutinated *Br. abortus* in dilutions of 1 : 600 and 1 : 150 respectively (see Figs. 1 and 2). In the cases of abortus fever, of which the highest titres were 1 : 2560 and 1 : 1600, there was at first a rapid and then a more gradual decline in the agglutinin content of the serum, but even ten months after recovery the titre was still sufficiently high (1 : 80 and 1 : 320 respectively) to allow a tentative diagnosis of previous abortus infection. The two farm-workers had, throughout the period of examination, a relatively high agglutinin-content without a definite history of past infection, so that in their case the presence and persistence of agglutinins may perhaps be attributed to their association with aborting cows.

FIG. 2.



Agglutinin content of serum of two byre workers. (Continuous line = Case 5, dotted line = Case 6.)

The *diagnostic titre*, which is the lowest positive dilution of serum to be regarded as indicative of infection, has been variously stated—from 1 : 10 to 1 : 200—by different workers. Our examination of the blood-sera of a sample (1522) of a general hospital population resulted in such a high proportion of wholly negative agglutination-reactions, and less than 2 per cent. of positive cases in a dilution of 1 : 20, that a titre of 20 standard agglutination units (S.A.U.) per c.cm.* was proposed as presumptive evidence of previous infection. This arbitrary standard was chosen in preference to the lower diagnostic titre of 10 S.A.U. per c.cm.—originally recommended by G. Dreyer for enteric infections and sponsored by the Medical Research Council for the diagnosis of undulant fever—largely because it was felt that the latter standard might include persons with a low concentration of agglutinins in their blood due to the ingestion of infected milk (King and Caldwell) or from other causes. We have found, for example, that the concentration of agglutinins in the blood of persons in close association with epizoötic abortion may be considerably higher than our diagnostic titre without necessarily indicating a past infection or the presence of an acute febrile illness. This finding has been confirmed by a recent report on the examination of 49 veterinary surgeons in America: the sera of more than half of these men, only three of whom gave histories of infection, agglutinated *Br. abortus* in dilutions varying from 1 : 50 to 1 : 500 (Huddleson and Johnson). While therefore 20 S.A.U. per c.cm. or a dilution of 1 : 50 may ordinarily be accepted as the diagnostic titre, a qualification may be made that consideration must always be given to the occupation and environment of the individual.

---

* Using the Oxford standard agglutinable cultures with a factor of 2·0–2·5, this corresponds to a dilution of the serum of 1 : 40–1 : 50.

Investigation of a Hospital Population.

To find the incidence of infection, all sera submitted for Wassermann reaction from the wards and dispensaries of the Glasgow Royal Infirmary during the six months November, 1929, to April, 1930, were tested for the presence of agglutinins to *Br. abortus*. The blood-sera of practically all patients admitted to the medical wards of the hospital are tested routinely for Wassermann reaction and only in the dispensaries and on the surgical side are cases selectively chosen; it followed that most of the sera examined came from a sample of the population suffering from a wide variety of medical ailments, including obscure pyrexias. Only 8·8 per cent. of these sera gave a positive Wassermann reaction.

Method.—All sera had been inactivated on the previous day by heating at 56° C. for half an hour. Dilutions of the sera of 1 : 10, 1 : 20, and 1 : 40, each of 0·5 c.cm. volume, were made in agglutination tubes, and to each tube there was added an equal amount of a suspension of *Br. abortus* prepared by emulsifying a 48-hours' serum-agar culture in normal saline, diluting the emulsion to an opacity equivalent to 1000 million organisms per c.cm., and heating at 60° C. for an hour. The final dilutions were therefore 1 : 20, 1 : 40, and 1 : 80; latterly only dilutions of 1 : 20 and 1 : 40 were used. The tubes were incubated in the water-bath at 56° C. for four and a half hours, and then allowed to stand at room temperature overnight before the readings were taken. If agglutination occurred with a serum in a dilution of 1 : 40 or over, the test was repeated on the following day with the Oxford standard agglutinable cultures, using Dreyer's method for the Widal reaction, and the results recorded in terms both of serum dilution and of standard agglutinin units. Sera which did not agglutinate the organism in dilutions beyond 1 : 20 were not re-tested.

It has been stated that non-specific agglutinins for *Br. melitensis* may be present in the blood of normal persons, but that these are destroyed by "inactivating" the serum (Nègre and Reynaud). Zone-phenomenon in the dilutions 1 : 25 and 1 : 50 was a feature of the agglutination-reactions in the present study when the sera from the patients with abortus fever were tested against the standard agglutinable cultures of *Br. abortus*; it did not occur with emulsions of the stock culture (N.C.T.C.) and is not likely to be a complication unless the titre is high.

Results.—No acute case of abortus fever was discovered during this routine examination, the cases quoted having been otherwise detected. Of 1522 sera tested, 25, or 1·6 per cent., gave a positive agglutination reaction in a dilution of 1 : 20, and 11 more reacted positively in dilutions of 1 : 40–1 : 80. When these 11 sera were further tested with the standard agglutinable culture, 7 (or 0·46 per cent. of the total) were positive in dilutions of 1 : 50 (= 20 S.A.U.), 1 : 125 (= 50 S.A.U.), and in one case 1 : 250 (=100 S.A.U.). Inquiry was made into the previous health of these seven patients and in several instances suggestive histories of recent ill-defined illness were given.

CASE 1, a town-bred medical student aged 30, had acute appendicitis 11 months ago; he was admitted with diarrhœa and bleeding from the bowel of two weeks' duration. He had night sweats, but they were practically apyrexial. Nothing was found on physical examination, and there was no history of previous febrile illness. He had had two injections of T.A.B. vaccine in 1916.

His agglutination reaction with *Br. abortus* was positive 1 : 125 (50 S.A.U.); two days later positive 1 : 250 (100 S.A.U.), but also positive 1 : 250 (62·5 S.A.U.) for *B. paratyphosus* B and 1 : 125 (15 S.A.U.) for *B. typhosus*. Examination of blood, fæces, and urine was negative. Re-tested ten days later, when the patient was well, the serum agglutinated *Br. abortus* in a dilution of 1 : 125 and *B. paratyphosus* B 1 : 250. A month after dismissal, the patient's serum was positive 1 : 50 with *Br. abortus* and 1 : 250 with *B. paratyphosus* B. That the agglutinins to *Br. abortus* were coagglutinins to *B. paratyphosus* B seems unlikely, as in eight other cases with positive Widal reactions to *B. paratyphosus* B there was no agglutination of *Br. abortus*.

CASE 2, a female town-dweller aged 51, was admitted with afebrile peripheral neuritis. This patient had been confined to bed for one month a year earlier with fever and some sweating, diagnosed as a chill. Her agglutination reaction (*Br. abortus*) was positive 1 : 125 (50 S.A.U.).

CASE 3, a female aged 26, was an epileptic of low intelligence. She was afebrile and had lived until recently on a farm in Ireland. There was no history of obscure [illegible] Her agglutination reaction (*Br. abortus*) was positive 1 : 125 (50 S.A.U.). This may have been due to the a[illegible] of the patient with cattle.

CASE 4, a female aged 20, a town-dweller, was [illegible] with bronchitis and a temperature of 99°–101° F. for a week. She had had appendicitis two years previously, followed immediately, while still in hospital, by "pleurisy" and irregular fever for five weeks. Her agglutination re[illegible] (*Br. abortus*) was positive 1 : 125 (65 S.A.U.).

Two of the remaining three cases gave histories of "influenza" 12 and 15 months previously, in one case followed by a generalised arthritis; their blood-sera each agglutinated *Br. abortus* in a dilution of 1 : 125 (65 S.A.U.). The last case, a diabetic, whose agglutination reaction with *Br. abortus* was positive 1 : 50, gave no history of previous obscure fever.

It must be admitted that the past histories of these patients, while suggestive in certain instances, do not afford absolute proof of infection, and the conclusions that even this small percentage of the community have had abortus fever must rest on the interpretation of the agglutination reaction.

In addition to these 1522 sera, there were 50 sera sent for Widal reaction from cases of continued fever; eight of these were subsequently shown to be paratyphoid B infections and one typhoid fever (positive Widal reaction *plus* isolation of the specific organism from the fæces). In all cases the sera reacted negatively with *Br. abortus*. Sera from eight cases of long-continued pyrexia (bacterial endocarditis, tuberculous infection, pyrexia of unknown origin) did not agglutinate *Br. abortus* in a dilution of 1 : 20. Meiser found, among 167 sera agglutinating one or other member of the enteric group, five which agglutinated *Br. abortus* in dilutions of 1 : 50–1 : 100. There was, however, no evidence that the phenomenon was due to coagglutinins, and the author concluded that it indicated a previous attack of undulant fever.

Investigation at an Infected Farm.

Several outbreaks of contagious abortion had occurred in the dairy-herd on the home-farm of the institution to which one of us is attached, an opportunity was afforded for carrying out some investigation on *Br. abortus* in persons consuming the milk-su[illegible] from the infected source or working in actual co[illegible] with the infected cattle. The investigation took the form of (*a*) agglutination tests with the sera of [illegible] picked sample of the community, and (*b*) inquiry in[illegible] the previous health and histories of individuals [illegible] whom a positive agglutination reaction was obtained.

The blood-sera of 112 cases were examined. Patients working in the byre and those whose duties brought them into actual contact with the animals were examined first, as they were deemed the likeliest to show a positive result. Subsequently patients engaged in general work on the farm were examined, and also other patients in different parts of the institution in whose diet milk was one of the main items. Milkers are unfortunately not included in any of the above groups. As they were private individuals, permission to take blood samples could not be obtained.

The *method* adopted for the agglutination reaction was similar to that described except that the Oxford standard agglutinable cultures were used throughout and a larger series of dilutions, viz., 1 : 25, 1 : 50, 1 : 100, 1 : 125, 1 : 150, 1 : 200, and 1 : 250 were used. In one case where complete agglutination occurred at

1 : 250 further dilution was made up to 1 : 1000. In cases giving a positive result with *Br. abortus* the agglutination reaction was repeated at a later date to verify the result and establish an accurate titre.

Results.—Of 112 cases—71 males and 41 females—ten showed agglutination of *Br. abortus* in a dilution of the serum of 1 : 25 or higher; they were all males. To show the close serological relationship between *Br. abortus* and *Br. melitensis*, the blood-sera of all positive cases were tested against a standard agglutinable culture of the latter organism (see Table).

TABLE *giving the Agglutinin-content for* Br. abortus *and* Br. melitensis *of the Sera of Individuals in Association with Aborting Cows.*

Case	Age.	*Br. abortus.*		*Br. melitensis.*		Occupation.
		S.A.U.*	Dilution.	S.A.U.	Dilution.	
1	57	20	1 : 50	20	1 : 50	Indoor house worker.

10	16	20	1 : 50	20	1 : 50	Sanatorium patient.

* S.A.U. = Standard agglutinin unit.

All the positive cases save one occurred among the farm workers, byre workers being chiefly affected. No agglutination reactions were obtained from the 41 female cases, although their milk-supply was the same as that of the byre workers. All the sera which agglutinated *Br. abortus* likewise agglutinated *Br. melitensis*, but not always to the same titre.

Inquiry into the previous health and histories of those in whom a positive reaction was obtained is not very enlightening, but it is suggestive that in certain cases histories of indefinite illness during the last three years were obtained. None of these cases has suffered recently from pyrexia—not even those whose sera agglutinated *Br. abortus* to a high titre—viz., 1 : 600 and 1 : 150. The latter two individuals had *their temperatures recorded twice* daily for a fortnight after the discovery of the positive Widal reaction but no variations were observed.

CASE 5, aged 27, was admitted on May 19th, 1924 (*Br. abortus* 1 : 600, *Br. melitensis* 1 : 450). He has always enjoyed fair health, but was laid up on Oct. 3rd, 1926, when he was found to be losing weight. He had no pains, cough, or sputum, and his appetite was good. His temperature was 98·4° F., his pulse-rate 70, and his respiration-rate 18. At present he is quite fit and out working daily.

CASE 6, aged 28, was admitted on March 13th, 1921. (*Br. abortus* 1 : 150, *Br. melitensis* 1 : 100.) He has been confined to bed on several occasions. On June 17th, 1925, he complained of pains in the legs and headache and his temperature was 100·2° F., his pulse-rate 98, and his respiration-rate 22. His evening temperature was always high—100·4°–101·2° F.—and his illness lasted three weeks. On Feb. 16th, 1926, he was laid up for a few days with abdominal pain. His general health is good at present and he is out working daily.

Three of the other cases gave a history of illness in April, 1926, but *no record is available of abortion being prevalent* among the cattle about that time.

It seems, therefore, that direct contact with infected cattle is more likely to cause agglutinin-formation, and presumably infection, among the human population than is the drinking of unsterilised infected cow's milk.

Excretion of Br. Abortus in Milk.

Mainly as a result of a rather severe epidemic of contagious abortion in a herd of dairy cows among which the infection had been occurring sporadically for several years, the management of the farm decided to institute a system of vaccination with living abortus cultures in an attempt to stamp out the infection. An opportunity was afforded us to examine the individual milks of the herd, a large number of which had received some time previously a single subcutaneous injection of living abortus vaccine. Information could therefore be obtained regarding: (*a*) infection of the udder in those cows which had aborted, with the consequent excretion of *Br. abortus* in the milk; (*b*) the continuity or intermittency of such excretion; and (*c*) the possibility of the excretion of *Br. abortus* in the milk after vaccination with live cultures.

It is believed that the udder is readily infected from the uterus and becomes the habitat of *Br. abortus* during the non-pregnant state (Schroeder and Cotton). Guinea-pig inoculation has shown that *Br. abortus* is present in a fair proportion of market milks, which are probably the source of infection in individuals not closely associated with cattle. Wilson and Nutt in 1926 concluded that 5·7 per cent. of single milks and 8·8 per cent. of mixed milks were infected, while pooled market milks in America have shown a higher incidence without, however, *disclosing what percentage of infected cows in* an individual herd excrete the organism in the milk. In the present investigation samples of milk were obtained from each member of a herd of 37 cows.

Method of Examination.—The samples of milk were received in sterile bottles on the day of milking. At first only the sediment of milk was injected, and for this purpose 100–150 c.cm. of each specimen was centrifuged at high speed and the resulting deposit, suspended in 2 c.cm. of normal saline, was injected intraperitoneally into adult guinea-pigs weighing 16–20 oz. In a later series of milks the supernatant cream obtained after spinning was used as *the inoculum, and in another series both cream and* sediment were injected, the object being to find whether the organism is more likely to be found in the cream, as has been asserted (Carpenter and Baker), or in the sediment. Each batch of guinea-pigs was killed after intervals of two to three months from the time of inoculation. Except for a first lot of ten guinea-pigs which were autopsied at once, the carcasses were kept at 0° C. until their blood-serum had been examined for the presence of agglutinins to *Br. abortus*. The animals were then autopsied, special care being taken in the examination of those whose sera had given a positive agglutination reaction.

Results.—In all, 51 *samples of milk from* 37 cows were tested; both the cream and sediment from five of these specimens were injected, making a total of 56 inoculated guinea-pigs. Five animals died within two weeks of inoculation; in three there was a streptococcal peritonitis and in two no cause for death was discovered. The rest remained well and did not lose weight. Agglutinins to *Br. abortus* were present in the serum of 9 out of 51 guinea-pigs killed 2–3 *months after inoculation*, the titres varying from 1 : 320 to 1 : 2560. When autopsied, three of these animals did not show any macroscopic morbid changes, and in the absence of the agglutination test would have been passed as not infected. In two of the other six there was enlargement of the superficial lumbar (sublumbar) glands but no gross changes in the spleen or elsewhere. The remaining four animals presented the classical picture of *Br. abortus* infection in the guinea-pig: enlargement of the lumbar glands and of the spleen, and throughout the substance of the spleen many greyish-white tubercles, not unlike those of a tuberculous infection but more "pearly" in appearance and, like the glands, not showing any tendency to caseation. Histologically these nodules appeared as collections of endothelial or epithelioid cells without giant-cells. Similar granulomata have been described in the liver, lungs, and testicles of infected guinea-pigs, but in only one of the present series were greyish nodules observed in the liver. *Br. abortus* was cultured from the spleens of two infected guinea-pigs, growth occurring on serum-agar slopes plugged with rubber stoppers after 3–4 days' incubation at 37° C.

These nine infected guinea-pigs represented the milks of four cows, or 10·8 per cent. of the number examined. From one cow there were three positive samples; both the cream and sediment of one of these samples were injected and both produced infection; from another cow there were two positive samples and again both the cream and the sediment of one of the specimens produced infection. Of the remaining two positive milks from two cows, in one the cream and in the other the sediment was used as the inoculum. It is evident, therefore, that the infecting organism may be present in both the cream and the sediment of the milk.

In order to find out if *Br. abortus* was being continuously excreted in the milk of infected cows, repeat samples were obtained from four cows which had aborted early in 1929 and again late in the same year. From one cow the organism was recovered by guinea-pig inoculation in the first, second, and fourth of four samples examined during a period of three months; from another in the first and third of three samples, a fourth specimen being discounted as the guinea-pig died six days after inoculation. From a third cow only the first of three specimens was positive, while all three specimens from the fourth cow were negative. The remaining positive milk was a second specimen from a cow which had aborted a year previously and was obtained when the cow was "going dry," being in calf. There is therefore some evidence of an intermittency in the excretion of *Br. abortus* in the milk, so that two or three specimens may be required to discover whether or not a cow is a milk carrier of the organism. On the other hand, an animal which has aborted may not excrete the organism in the milk.

Protection by Vaccines.

McFadyean and Stockman in 1913 first demonstrated the efficacy of a vaccine of living *Br. abortus* as compared with killed cultures to protect healthy cows against abortion. Recent work in America (Buck and Creech) has indicated that the usefulness of the living vaccine is limited to its employment as a prophylactic measure against epizoötic abortion, and that it has little or no value in the treatment of established infection. There is even a danger, it is said, that cattle inoculated with living vaccine may become chronic milk carriers of the organism (Carpenter). Consequently vaccination has been largely abandoned in America and a system of eradication of the positive reactors adopted.

It is difficult to assess the value of living vaccines in lessening the incidence of abortion in an infected herd, since cows which have aborted once do not readily abort a second time, although they may still be carriers of *Br. abortus*. However, it is important to inquire whether vaccination is actually harmful, either by predisposing to subsequent abortion or by producing infection and a milk carrier condition in previously healthy cows. The following Table illustrates the results obtained in the herd under consideration.

Cows inoculated, 30.

Previous abortion, 18 (4 positive milks).
Subsequent abortion, 4
(3 of the 4 positive milks belong to this group).

No previous abortion, 12 (no positive milks).
Subsequent abortion, 0.

It is seen that in 12 healthy cows the inoculation of living *Br. abortus* vaccine has not resulted either in infection as indicated by abortion (all these cows have since had full-time calves) or in excretion of the organism in the milk. Among 18 cows with history of previous abortion there were four positive milks (22 per cent.), which compares favourably with the findings of Winkler, who had 13 positive milks (40 per cent.) from 32 uninoculated cows which had recently aborted. The occurrence in this group of four subsequent abortions is in keeping with the general experience that about 20 per cent. of cows abort a second time. There is therefore no evidence from the present work that the use of living vaccines of *Br. abortus* is harmful either to infected or healthy cows.

Conclusions.

(1) The incidence of *Br. abortus* infection as judged by the agglutination test was so low (less than 0·5 per cent.) in a sample of a general hospital population that the probability of its being a common infection in this country seems remote. (2) Association with infected cattle—e.g., by dairymen, farmers, and veterinary surgeons—may result in the formation in the blood of agglutinins to *Br. abortus* without necessarily producing infection. On the other hand, drinking infected milk does not seem to result in agglutinin-formation to any extent. (3) Only a proportion of infected cows (22 per cent. in this series) excrete *Br. abortus* in the milk. The excretion may be intermittent and the organism is present both in the cream and in the milk sediment. (4) Inoculation of a dairy herd with living *Br. abortus* vaccine, if not of curative value to infected cows, is not harmful to healthy animals and in the latter is probably a useful prophylactic measure. (5) Guinea-pigs infected with *Br. abortus* by milk inoculation may not show any gross pathological changes in the tissues, and the diagnosis of abortus infection in the guinea-pig rests primarily on the agglutination test.

MAXIMAL RETICULOCYTE RESPONSES FROM INTRAVENOUS INJECTION OF A LIVER EXTRACT.

BY WILLIAM B. CASTLE, M.D.,

AND

F. H. LASKEY TAYLOR, PH.D.

(From the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard), Boston City Hospital and the Department of Medicine, Harvard Medical School.)

IN the early stages of the chemical fractionation of liver, begun in an effort to isolate the active principle effective in pernicious anæmia, Cohn, Minot, and their associates[1] produced an active extract, the so-called "fraction G" which could be readily prepared and was found to be eminently satisfactory in the treatment of pernicious anæmia. Later Cohn,[2] West,[3] and their respective associates produced numerous experimental fractions which were given by mouth; but it was not until Cohn[4] was able to prepare fractions which gave no specific protein reactions and which had no reducing effect on the blood pressure of animals that it was considered possible to administer the active principle intravenously to patients. After this stage of the work had been reached Cohn,[5] West,[6] and their respective associates prepared many potent fractions which were injected intravenously in patients.

The methods of preparing fractions then regarded as suitable for intravenous use were technically difficult and sufficiently laborious to render it impractical to prepare more than the small amounts of experimental fractions utilised in the search for the active principle. With an entirely different objective—namely, to discover the least number of steps necessary to produce from liver a potent fraction that could be injected intravenously with safety—we have adapted to our practical problem the methods of preparing effective liver fractions contributed by these investigators. The original fraction G of Cohn, Minot, and their associates[1] was precipitated in 95 per cent. alcohol from the concentrated water-soluble extractives of minced liver, from which extractives the proteins had previously been removed by iso-electric precipitation and heat. Although the precipitate so formed was readily soluble in water, and had been freed of proteins and, by alcohol, of the larger polypeptide molecules possibly capable of producing allergic phenomena if intravenously administered, it was shown to contain a blood-pressure lowering substance.[2] For this reason, only subfractions largely or entirely free of the depressor substance were given intravenously to patients. Nevertheless, because of the relative ease of preparation of this fraction G and because the objection to its intravenous use seemed to be based, in theory at least, solely on its blood-pressure lowering properties, it appeared to us a suitable starting-point for our studies.

Depressor Action of Extracts.

In the course of observations on rabbits and cats carried out with several derivatives of this fraction, the experience of Cohn and his associates[2 5] was confirmed in that it was found to be impossible except by difficult and expensive procedures to eliminate or greatly reduce the blood pressure lowering substance. On the other hand, it was at once noted that the persistence of this depressor effect in cats was always short (1 to 2 minutes) and numerous observations showed that the magnitude of the effect could be easily controlled by varying the rate of injection of the material. For intravenous injection the derivatives of fraction G which were prepared by us appeared therefore to have no advantage over fraction G itself. Further observations then showed that aside from a transient effect on blood pressure aqueous solutions of the original fraction G had no evident deleterious action on rabbits when injected daily for several days in amounts 0·2 g. per kg. of body-weight. On this basis, and because of the previous successful experience of Cohn, McMeekin, and Minot[4 5] with intravenous injections of related fractions, it was considered safe to try the effect on a pernicious anæmia patient of a single intravenous injection of an extract containing a little over 0·1 g. per kg. of body-weight of fraction G dissolved, after washing with ether, in physiological salt solution. This solution was so prepared that 20 c.cm. contained the amount of material derived from 100 g. of liver—i.e., about 4·5 g. of a commerical preparation of fraction G. After solution a small insoluble residue was removed by careful filtration or centrifuging, and the resulting clear dark reddish-brown liquid sterilised by boiling for five minutes.

The effect of the blood pressure of this patient and of others since injected intravenously with this material was found to be similar to that already observed in cats. Both systolic and diastolic pressures were decidedly lowered if the extract was injected faster than at a rate of 4 c.cm. per minute. The effect was more marked when the patients were more anæmic or had a lower original blood pressure; but in all instances the blood pressure returned to its original level within one or two minutes after the termination of the injection. The immediate effects on blood pressure were evidently of no importance if the rate of the injection was governed by following the blood pressure or even after a little experience by observing the colour of the patient's face and the character of the pulse.

All the patients stated that their faces felt hot during the injection; and they looked flushed. One patient who gave a history of bronchial asthma had an attack of severe dyspnœa with some increase of the râles in the lungs at the termination of the injection. This effect suggests a parallel to the observations of similar symptoms with the intravenous injection of histamine which Weiss, Robb, and Blumgart[7] have reported as occurring in cases of pulmonary emphysema or bronchial spasm. The attack was promptly abated by a subcutaneous injection of 0·5 c.cm. of adrenalin 1/1000. It recurred at a second injection of the liver extract and was again promptly relieved by adrenalin, and was apparently prevented at a third injection by adrenalin administered just before the injection began. In one patient a moderately severe chill occurred about half an hour after the injection was completed, and later the temperature rose to 103° F. There were no significant febrile reactions in the other patients. It is a common experience that the intravenous injection of many substances, even salt solution, into certain pernicious anæmia patients, especially those with low red blood-cell counts, may produce a rigor and febrile reaction. Skin tests and conjunctival instillation of the extract performed in one patient ten days after the first gross changes in the spleen or elsewhere. The remaining four animals presented the classical picture of *Br. abortus* infection in the guinea-pig: enlargement of the lumbar glands and of the spleen, and throughout the substance of the spleen many greyish-white tubercles, not unlike those of a tuberculous infection but more "pearly" in appearance and, like the glands, not showing any tendency to caseation. Histologically these nodules appeared as collections of endothelial or epithelioid cells without giant-cells. Similar granulomata have been described in the liver, lungs, and testicles of infected guinea-pigs, but in only one of the present series were greyish nodules observed in the liver. *Br. abortus* was cultured from the spleens of two infected guinea-pigs, growth occurring on serum-agar slopes plugged with rubber stoppers after 3–4 days' incubation at 37° C.

These nine infected guinea-pigs represented the milks of four cows, or 10·8 per cent. of the number examined. From one cow there were three positive samples; both the cream and sediment of one of these samples were injected and both produced infection; from another cow there were two positive samples and again both the cream and the sediment of one of the specimens produced infection. Of the remaining two positive milks from two cows, in one the cream and in the other the sediment was used as the inoculum. It is evident, therefore, that the infecting organism may be present in both the cream and the sediment of the milk.

In order to find out if *Br. abortus* was being continuously excreted in the milk of infected cows, repeat samples were obtained from four cows which had aborted early in 1929 and again late in the same year. From one cow the organism was recovered by guinea-pig inoculation in the first, second, and fourth of four samples examined during a period of three months; from another in the first and third of three samples, a fourth specimen being discounted as the guinea-pig died six days after inoculation. From a third cow only the first of three specimens was positive, while all three specimens from the fourth cow were negative. The remaining positive milk was a second specimen from a cow which had aborted a year previously and was obtained when the cow was "going dry," being in calf. There is therefore some evidence of an intermittency in the excretion of *Br. abortus* in the milk, so that two or three specimens may be required to discover whether or not a cow is a milk carrier of the organism. On the other hand, an animal which has aborted may not excrete the organism in the milk.

Protection by Vaccines.

McFadyean and Stockman in 1913 first demonstrated the efficacy of a vaccine of living *Br. abortus* as compared with killed cultures to protect healthy cows against abortion. Recent work in America (Buck and Creech) has indicated that the usefulness of the living vaccine is limited to its employment as a prophylactic measure against epizoötic abortion, and that it has little or no value in the treatment of established infection. There is even a danger, it is said, that cattle inoculated with living vaccine may become chronic milk carriers of the organism (Carpenter). Consequently vaccination has been largely abandoned in America and a system of eradication of the positive reactors adopted.

It is difficult to assess the value of living vaccines in lessening the incidence of abortion in an infected herd, since cows which have aborted once do not readily abort a second time, although they may still be carriers of *Br. abortus*. However, it is important to inquire whether vaccination is actually harmful, either by predisposing to subsequent abortion or by producing infection and a milk carrier condition in previously healthy cows. The following Table illustrates the results obtained in the herd under consideration.

Cows inoculated, 30.	
Previous abortion, 18 (4 positive milks).	No previous abortion, 12 (no positive milks).
Subsequent abortion, 4	Subsequent abortion, 0.
(3 of the 4 positive milks belong to this group).	

It is seen that in 12 healthy cows the inoculation of living *Br. abortus* vaccine has not resulted either in infection as indicated by abortion (all these cows have since had full-time calves) or in excretion of the organism in the milk. Among 18 cows with history of previous abortion there were four positive milks (22 per cent.), which compares favourably with the findings of Winkler, who had 13 positive milks (40 per cent.) from 32 uninoculated cows which had recently aborted. The occurrence in this group of four subsequent abortions is in keeping with the general experience that about 20 per cent. of cows abort a second time. There is therefore no evidence from the present work that the use of living vaccines of *Br. abortus* is harmful either to infected or healthy cows.

Conclusions.

(1) The incidence of *Br. abortus* infection as judged by the agglutination test was so low (less than 0·5 per cent.) in a sample of a general hospital population that the probability of its being a common infection in this country seems remote. (2) Association with infected cattle—e.g., by dairymen, farmers, and veterinary surgeons—may result in the formation in the blood of agglutinins to *Br. abortus* without necessarily producing infection. On the other hand, drinking infected milk does not seem to result in agglutinin-formation to any extent. (3) Only a proportion of infected cows (22 per cent. in this series) excrete *Br. abortus* in the milk. The excretion may be intermittent and the organism is present both in the cream and in the milk sediment. (4) Inoculation of a dairy herd with living *Br. abortus* vaccine, if not of curative value to infected cows, is not harmful to healthy animals and in the latter is probably a useful prophylactic measure. (5) Guinea-pigs infected with *Br. abortus* by milk inoculation may not show any gross pathological changes in the tissues, and the diagnosis of abortus infection in the guinea-pig rests primarily on the agglutination test.

(20 g. dry weight) to about 0·10 g. in the form of the active substance of West and Howe.[13] The greatest concentration so far obtained must therefore be about 200-fold.

Ætiological Significance.

The problem of securing a satisfactory liver extract readily available for intravenous use was undertaken largely for the purpose of extending studies already made upon the ætiologic relationship of gastro-intestinal pathology to pernicious anæmia. A specific type of gastric defect in patients with pernicious anæmia has already been demonstrated by one of us,[8] and is regarded as the factor of primary importance in the development of the disease. The suggestion was made of the existence of a defect of absorption of hæmatopoietic factors contained in the food or possibly formed to a certain extent in the stomach of certain atypical cases of pernicious anæmia, especially those associated with chronic disturbances of the lower intestines and an apparently normal gastric function. In the treatment of one of the cases referred to above the amount of liver extract No. 343 N.N.R. derived from 3000 g. of liver when given by mouth during a period of ten days had relatively little effect on blood formation (see Figure). Given thus to the average case of pernicious anæmia, that amount of potent substance should have produced a reticulocyte response approximately equal to that subsequently obtained from a single intravenous administration of the extract derived from 100 g. of liver. The simplest, but not the only explanation of this insignificant result from oral administration, is that it was caused by a relative impermeability of the intestinal wall of this particular patient who, however, responded like the other patients to the active principle when given parenterally. To what extent such a condition is present in all cases of pernicious anæmia or even as a normal physiological condition in respect to the absorption of the active principle of liver is at present under investigation. Thus it is believed that the demonstration of the strikingly greater effectiveness of the active principle when administered intravenously than when given by mouth is possibly of significance in the ætiology of the disease.

Clinical Use of Intravenous Extracts.

Finally, it would appear that the extract described is of potential therapeutic significance. The response to the active principle of liver may be hastened by its intravenous administration[5] and so be of life-saving value to the very sick patient. In the so-called resistant cases, as exemplified by the patient just referred to, the method would seem to have valuable possibilities. In the treatment of lesions of the spinal cord this method of administering the active principle or related substances such as vitamin B[16] may be of use. However, it cannot be too strongly emphasised at this time that the therapeutic possibilities of the extract described in this preliminary report are still largely unknown and that the intravenous injection of any substance has potential dangers which cannot always be foreseen. Excellent sources of potent substance highly effective and easily administered by mouth are readily available even to the impecunious patient.[17] The immediate therapeutic need is not for new sources of the active principle, but for persistence in the use of sufficient quantities of those already available.

Summary.

1. A readily prepared extract of liver (fraction G) hitherto administered by mouth has been found suitable for intravenous injection and highly potent in pernicious anæmia.

2. Maximal reticulocyte responses were obtained from a single intravenous injection of the amount of extract derived from 100 g. of liver. One of the patients so treated had failed to respond satisfactorily to the previous oral administration of a similar extract derived from 3000 g. of liver given within a period of ten days.

3. The possible ætiologic and therapeutic significance of these observations is discussed.

It is a pleasure to acknowledge our indebtedness to the staff of the medical services of the Rhode Island Hospital, Providence—in particular to Dr. Alexander M. Burgess and Dr. Charles F. Gormly—for permission to study patients on their services. We are also indebted to Dr. Herman A. Lawson, Dr. Theodore Davies, and Dr. Nicholas Sarro of that hospital for their kind coöperation in making these observations. The technical assistance of Miss Margaret Evans and of Miss Charlotte Nichlan is gratefully acknowledged.

METROPOLITAN CONVALESCENT INSTITUTION.—This institution, which has three homes for adults and one for children, and a total of 588 beds, last year received considerably fewer patients than formerly. At the annual meeting Mr. Stewart Oxley, the chairman, said that it was difficult to explain the reason of the diminution, the more especially since the institution is of great value to many hospitals who are able to send cases in need of continued surgical treatment, thereby more speedily releasing their beds. Last year there were 5563 admissions. There was a considerable fall in income, which is accounted for by legacies, upon which the charity is much dependent, having amounted only to £25.

QUEEN VICTORIA MEMORIAL HOSPITAL, NICE.—The Duke of Connaught, who was accompanied by Princess Louise, Duchess of Argyll, recently opened a new nurses' home at this hospital. The Duke, who is the Patron, stated in his speech that in spite of the extra accommodation every bed in the hospital was occupied; every nurse on the outside nursing staff was occupied; to date, there had been 50 more admissions than last year; the four isolation annexes had been used simultaneously for the treatment of four different contagious diseases; and since the beginning of that season there had been 80 major operations. The sum of £15,000 that was obtained two years ago has been spent upon essentials to bring the hospital up to date, but a new theatre and X ray room are urgently needed. The new buildings have been provided by an anonymous American benefactor.

POST-OPERATIVE VOMITING.

By Bessie E. Cook, M.B. Manch.,
HON. ANÆSTHETIST, DONCASTER ROYAL INFIRMARY.

It is a popular belief, and one shared to a large extent by the profession, that to be sick for several days is the correct thing for any patient after having a general anæsthetic. It is certainly an observation founded on common experience, and the view that blame should be laid at the door of the agent used is reflected in the term "post-anæsthetic" vomiting. Plenty of theories as to how it happens are offered, many of them well supported by evidence; the chief are: local causes affecting the stomach, swallowed or excreted anæsthetic, and general changes in the blood stream, acting on the centre, either an acidosis or an anoxæmia.[3 4 5]

For over a year the anæsthetics given at the Rotherham Hospital have been more varied than is the case at most provincial infirmaries, since approximately one-half the patients have been given gas and oxygen with or without a little ether, and the rest have had chloroform and ether mixture, or pure ether, with no oxygen except in emergency. It seemed a waste of interesting material not to examine the records and see what differences could be found, and whether any useful conclusions might be drawn, especially since it has been claimed on the other side of the Atlantic that after-sickness has been greatly reduced since the increase in the use of nitrous oxide for major operations.[1 2] Accordingly, a number of cases were taken seriatim from the operation book, classified under their respective anæsthetics and subdivided as will be described later, and then their after-histories were followed up in the ward records. The results obtained have been tabulated in each class according to whether the patient did not vomit at all or was sick on one, two, or more days, which seemed the simplest test of the amount of general systemic upset. For convenience, cases which were only sick once are included with the "first 12 hours" section. As the fact soon emerged that the percentage rate of sickness in men was less than that in women, it was necessary to work out the rates separately and then take the average of the male and female rates in each class, so as to avoid any error due to varying proportions between the number of each sex.

Various Classes of Operation.

The operations have been classified according to their sites and severity. Class 1 is that of abdominal sections, including gall-bladder cases, gastro-enterostomies, hysterectomies, appendicectomies, and salpingectomies.

TABLE I. (CLASS 1).

Cases vomiting.	ETHER.			NITROUS OXIDE.

" 4 or more ..	0	4	1·53	0	4	1·62
Total	93	120	—	77	123	—

M. = male; F. = female.

Those cases which, having had ether, were sick for longer periods than three days comprise one patient whose operation was a salpingectomy and remov of the appendix, with drainage, and who went vomiting for seven days, dying on the twelfth da with fluid in the chest; one hysterectomy, appendix with drainage, and a double salpingectomy. The gas cases were two hysterectomies, one gastri carcinoma for which on laparotomy nothing could b done, and a pregnancy, so that two of them would probably have vomited without an operation at all.

Class 2, the herniæ, while not, as a rule, involving in men such drastic manipulation of abdominal organs and peritoneum, still have their own special area in which *trauma is likely to produce disturbance*, viz., the cord, and it will be seen that the vomiting rate remains high in this section, being, indee noticeably higher than that for laparotomies, whil the majority of herniæ in females in this series ventral and so in many cases practically abdominal.

Here the single patient who vomited on the sec day did so once only (and only twice the first day He had had a cystoscopy. A month previous he ha an appendicectomy performed under chlorofor and ether, when he was sick six times in the 48 hours

The last class is a miscellaneous one comprising al the rest, from tonsillectomies in adults to radical amputations for scirrhus. The latter were include here as there were not sufficient of them to form a class by themselves.

Over the whole series—500 patients who had ether, and an equal number who were given gas and oxygen—the average on all classes totals 43¼ per cent. who were not sick at all among the former, and 56 per cent. among the latter. These results have been shown in the form of graphs; and we were at once impressed by the close resemblance between the curves of the two *anæsthetics, although there is in every case a* slight but definite advantage on the side of gas and oxygen (Fig. 1).

Analysis of Factors.

Considering the differences between them, their rate of elimination, their relative effects on hepatic function and metabolic activities and also on gastrointestinal movements (under gas-oxygen anæsthesia these are found to be stimulated) [3] and in this series the fact that oxygen was given as a routine to the one group and not at all to the others, as well as differences in premedication, it was necessary to seek another factor common to both. Had anæsthesia been the principal cause of the vomiting, there is no reason why one class of operation should be followed by more sickness than another, except the duration of it and, in answer to this, many of the hernia and appendix operations only *occupied 20 minutes or so.* There are two factors concerned in producing similar results: anæsthetics and operations. There is a good deal of difference between the former; the latter are the same in each class. In view of this similarity of result, it appears reasonable to give more blame to the operation and less to the drug, for the vomiting that occurs. But because there is a degree of difference in the results, evidently the anæsthetic is a factor, though by no means the only one. It is quite in accord with this view that local and spinal anæsthesia, preventing impulses from the field of operation from reaching the brain, are followed by so little sickness. It is partly a question of depth of anæsthesia, but since surgeons who ask for very deep anæsthesia are usually those whose technique would produce reflex signs in patients not quite so deep, probably both causes, *surgical trauma and excessive anæsthesia, may be in* action at one and the same time. Some support is given to the theory that the operation is an important factor by *an examination of the percentages obtained* by different surgeons. The ether abdominal group was composed of the cases of five different operators and, had the anæsthetic been the cause of the sickness, the *figures should be about the same for each* operator. The numbers of cases were not great, so the results are suggestive but in no way conclusive. The average of cases in this group who had no sickness is 29·8 per cent. Surgeons *A* and *B* were very close to this figure, the one with 29·4 per cent. and the other with 28·8 per cent. Surgeons *C* and *D* had lower rates, only 21·4 per cent. and 15·3 per cent. respectively, while surgeon *E* holds the record of 32·4 per cent. not sick.

*One might almost venture the statement that, given a patient in fairly good condition and not too tempera*mental, an anæsthetic, per se, does not cause vomiting unless given in excess. A serious operation plus an anæsthetic may, and often does, cause vomiting, and a serious operation plus an excessive anæsthetic can be almost guaranteed to produce any amount of vomiting, except only when the unfortunate patient is too ill to be capable of reacting in that way.

To show that the personality of the patient counts for something, an out-patient in my experience some years ago was given ether for 20 minutes, for the disimpaction of an obstinate Colles's fracture. Later in the day he went home, escorted by his son, and on his next attendance we were informed that the patient had enjoyed for his tea the same afternoon two pork chops, which had been prepared for the son; the latter, who had merely waited inside the hospital, had found he had quite lost any desire for the meal.

Stay in Hospital.—It is claimed in the States that the gas patients are able to leave hospital a number of days sooner than those who have had ether. At Rotherham, as at other hospitals, many factors are *taken into account,* such as the state of the waiting list, the possibilities of home nursing, and the amount of time that the patient's own doctor may be able to devote to him. But these factors applied equally to patients receiving either anæsthetic; no class distinction governed the selection, so that when it is found that the gas cases, in similar groups of operations, actually have gone home on the average a

FIG. I.

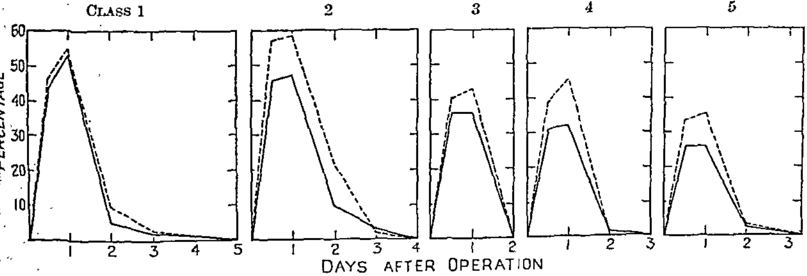

Chart showing the percentage incidence of vomiting after nitrous oxide (continuous line) and ether (dotted line) in five classes of case. 1 = abdominal; 2 = hernia; 3 = fractures; 4 = *perineal*; 5 = *miscellaneous.*

day or more sooner, it seems that their progress is really more rapid than those who have had ether. The figures for a group of clean appendix cases, uncomplicated, and for the hernia class, are as shown in Table VI.

TABLE VI.

—		Total cases.	Total days.	Average stay.
Appendix cases given	gas ..	62	794	11·2
	ether ..	80	1072	13·5
Hernia cases given	gas ..	72	974	13·5
	ether ..	47	726	15·5

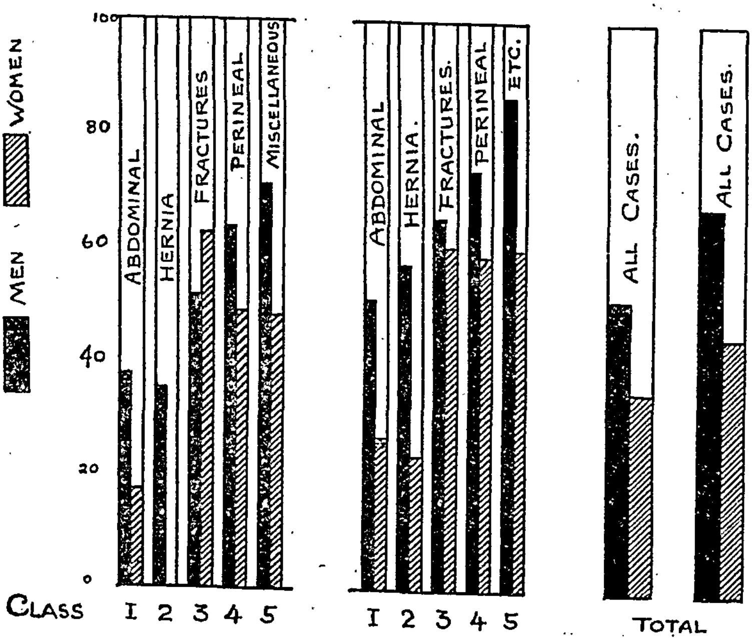
In addition to this, both the staff [4] and patients who have previously had ether confirm the great difference in the immediate well-being after operation, a difference which cannot be demonstrated in terms of statistics. The after-sickness is of a different quality. With ether there is only too often a heavy stuporose nausea for several days, even if there is no actual vomiting, and the taste of the drug lingers, since its complete elimination may take a week. With gas and oxygen, eliminated within a few seconds of the close of administration, the taste appears to be entirely absent, and it seems at least a possibility that some of the sickness occurring after gas could fairly be attributed to the fact that patients are sooner able to move voluntarily in bed. Alternatively, since, when it does happen, *it is frequently two or three times* during the first night—that is, some time after elimination of the agent—whereas, in ether it is during elimination, it suggests that it may come when the effect of the morphia is passing off, leaving the pain stimuli from the field of operation in possession. This is contrary to the experience of Macklin,[5] who finds sickness to occur immediately after the operation. As to earlier movement, many people find that keeping very still is of value when crossing the Channel.

Recovery.—Sir Francis Shipway writes, after referring to the dislike of losing one's conscious self, "Equally disliked is the return from profound anæsthesia with its alternating periods of nightmare and reality." [6] Although he was describing ether in contrast with avertin, his words apply equally well to the contrast between ether and gas cases, since after gas they are sufficiently wide awake to respond to questions by the time they leave the table. They have so little recollection of induction that at that moment the chief difficulty is to convince them that the dreaded operation is a thing of the past and, thanks to pr medication, by the next day they have little recollection of coming to the theatre. The ward sisters that they prefer their patients to have gas, as are so much sooner able to look after themselves. T preliminary drug used was, for the gas cases, ei 1 c.cm. of opoidine, or gr. ¼ of morphia with scop amine, so that by the time they left the wards th were somewhat drowsy, although quite ready t talk. Ether cases usually had atropine only.

Sex Differences.—Vomiting is only one-third t one-half as frequent in men as in women. While th nervous and endocrine systems in women are thing of most delicate balance, easily affected, and unconsciously, both by psychic and physic trauma, the stomachs of men are frequently in bett training to be insusceptible to foreign substance such as would produce nausea in digestive tracts le case-hardened, and so they require greater to start it. Of greater muscular development, especially if accustomed to generous rations nicotine and alcohol, such patients require larg amounts of anæsthetic; but in them, unless there definite gastric trouble, vomiting is relatively A reference to the previous tables shows the for each class, and Fig. 2 gives the proportion of ea sex which did not vomit. In each case there is rath less sickness under gas and oxygen. Only in Class the fractures, this relation apparently does not hold the reason may lie in the fact that the ladies Rotherham so seldom came under the anæsthetist care on account of those injuries that it was imp to collect sufficient cases to give reliable data. were only five females in one division and eight in th other.

Pulmonary Complications.—If women are liable to vomit, men are more liable to coug It seemed probable that the frequency of ch complications varied according to the time year, so that cases were put into two groups, one covering the period October to April, the May to Septer ber, a sort average d sion into and war weather. T cases we further divi according to and any ki of cough, an epidem coryza to broncho-p monia lastin a week or m has been cluded when th greater pro tion of cough amongst me was proved numerically Probably th is due to th fact that, up to now, men generally need good deal anæsthetic tha women. The figures to some

FIG. 2.



Ether. Gas and oxygen. Ether. N_2O.

Diagram showing percentage of cases in which there was no vomiting at all.

extent confirm the seasonal variation, but bring out even more strongly the fact that nitrous oxide is 50 per cent. less likely to be followed by chest complications than ether when given intensively. This is shown by the detail that, winter and summer, the ratio between the percentage of men and women having coughs is, after ether, approximately as 4 to 1, and, after gas, as 2 to 1, other conditions being equal. Both gas and ether cases are nursed in the same wards, but there is a tendency to ensure that "bad risk" cases, especially those with pre-operative lung and cardiac troubles, should get gas and oxygen owing to its lesser toxicity. It is evident that ether in high concentrations has a greater tendency to affect the lungs than has gas (Table VII.).

TABLE VII.

—	October–April. Total coughs and *per cent.*		May–September. Total coughs and *per cent.*
(1) GAS ..	Men	.. 10 in 42 (23·8)	5 in 25 (20)
	Women	.. 10 in 84 (11·9)	2 in 22 (9)
(2) ETHER	Men	.. 26 in 45 (57·7)	11 in 38 (28·9)
	Women	.. 10 in 69 (14·4)	3 in 40 (7·5)

Other Workers' Results.—Few statistics are available of the amount of vomiting which is usual. In Ross and Fairlie's text-book, J. F. R. Smith's figures are quoted as follows: In a gynæcological hospital, which would correspond to Class 4 in this series, only 20 per cent. of cases were sick at all, and about one-third of these "continued to vomit for periods varying from ten hours to three days." These rates are lower than those given by other writers. C. Potter, demonstrating great reduction in the amount of sickness from the use of glucose previous to operation, obtained, in a series of abdominal cases, 51 per cent. of cases not sick where glucose had been given, and writes in the same paper: "Trauma is an important factor (in causing vomiting). How many of us have been nauseated by smashing a finger? How much more, then, from rough handling of intestine?" and, comparing these results with a group of eight cases of operation on the extremities, which showed 100 per cent. not sick, she concludes: "The magnitude of the operation is a contributing factor to the vomiting as well as the anæsthetic." Most standard books appear to regard it as a more or less necessary evil in the majority of cases, and content themselves with giving various suggestions for its treatment. But many writers refer to the comparative infrequency of sickness with gas and oxygen, without mentioning numbers.

Death-rate.—The death-rate in the series numbered 20 in the gas, and 30 in the ether division. Neither division produced a death on the table, but whereas in the first 24 hours after operation two gas patients died, there were seven casualties in the ether division over the same period. It is not always possible to acquit the anæsthetic of all responsibility for deaths occurring after longer periods, apart from chest complications, since the results of profound circulatory and respiratory disturbances cannot be quickly repaired in a debilitated patient.

Conclusions.

If, as seems at least a possibility, trauma is of so great importance in even the minor discomforts after operation, this is a plea for gentler and still gentler technique in surgery. Gentler technique on the surgeon's part means that he need not complain even though gas and oxygen be used, and it is still of value when ether is given, since a less deep anæsthesia is needed. The use of gas means that the patients' respiratory and circulatory systems do not suffer so great an upset, and their organs, receiving less trauma from the velvet touch of the gas-accustomed surgeon, recover sooner from the necessary minimum of handling. Thus the patient gains in two ways and the surgeon gains in the long run, if he is prepared to pay the price of success. Nobody now claims for gas and oxygen that it gives greater access to the surgeon, but it can give him greater ease of mind as to its toxicity and chances of producing shock, and it affords—what, after all, should be the chief consideration—greater well-being to the patient in two trying and intensely important periods of time, the few minutes before consciousness is lost and the few days immediately following its return.

My thanks are due to Dr. E. J. Chambers, and others of the Rotherham Hospital, who have given me all assistance in the collection of these notes.

CLINICAL AND LABORATORY NOTES

NECROSIS OF THE RIGHT KIDNEY

IN A CASE OF CEREBRO-SPINAL FEVER.

BY J. D. ALLAN GRAY, M.B., B.SC., M.R.C.P. EDIN., D.P.H.,
ASSISTANT CITY BACTERIOLOGIST, LIVERPOOL.

THE following case is one of almost complete necrosis of the right kidney associated with cerebro-spinal fever. It is interesting because there were no clinical features relating to the urinary system.

A baby, apparently healthy until 4 months old, developed vomiting and constipation. At 5 months he was admitted to the Royal Hospital for Sick Children, Edinburgh. At first, physical examination was completely negative, but gradually he showed a picture typical of cerebro-spinal fever, and died ten days after admission. There was no clinical abnormality attributable to the urinary system. For two days before death albuminuria was noted.

At autopsy all the typical appearances of a purulent meningitis with hypostatic congestion of the lungs were present.

The site of the right kidney was occupied by a firm nodular mass of tissue which, on section, showed a kidney-shaped area ¾ in. by ½ in. in size, surrounded by a zone of congestion. The left kidney presented no pathological feature to the naked eye and was not unduly large for the size of the body. The renal artery of the right side, although smaller than that of the left, was not occluded. Both ureters were identified and both opened into the bladder.

Microscopical examination.—The kidney-shaped area in the site of the right kidney consisted of kidney tissue which had necrosed and undergone hyaline degeneration; only very few glomeruli and tubules could be distinguished. A considerable amount of calcareous material was present. The tissue round the actual kidney substance consisted of suprarenal gland and adipose tissue. The left kidney was very congested and showed toxic changes.

The right kidney was of about the average size of a kidney in a fœtus of 5–9 months. Allowing for a certain shrinkage in size, it seems justifiable therefore, to assume that at some time in the later months of intra-uterine life or soon after birth this kidney necrosed. The most likely cause of the necrosis seems to be infarction. No occlusion of the renal artery, however, was found. The albuminuria two days before death can be fully accounted for by the toxæmia, so that we are left with a negative urinary history. The left kidney must have been able to compensate for the cessation of function in the right organ.

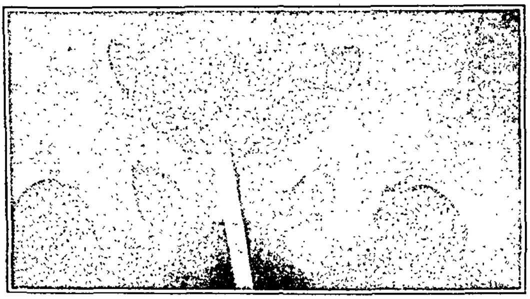
I have to thank Dr. Charles McNeil and Dr. Agnes R. Macgregor for permission to publish the case.

CATHETERISATION OF THE EJACULATORY DUCTS AND A SEMINAL VESICULOGRAM.

BY FRANK KIDD, M.CHIR. CAMB., F.R.C.S. ENG.,
CONSULTING SURGEON TO ST. PAUL'S HOSPITAL, LONDON.

A MAN, aged 26, had suffered during the last two years from two attacks of gonococcal urethritis. During the first attack he had left epididymitis, during the second attack right epididymitis. The disease was finally cured by means of prostatic and vesicular massage, irrigations, and the passage of large bougies.

The patient wished to know if he was fertile. He was examined with a McCarthy pan-endoscope and the attachments devised by McCarthy for catheterising the ejaculatory ducts. A perfect view was obtained of the verumontanum. The left ejaculatory duct orifice was closed and would not admit a catheter, the right ejaculatory duct orifice was patent and admitted a catheter readily. Sodium iodide was injected up the catheter and a radiogram was taken (see Figure), which shows that the right vas, the right vesicle, and the right ejaculatory duct are patent. Specimens of the spermatic fluid contained living spermatozoa, and it became clear that these were coming from the right testicle only.



Radiogram showing sodium iodide injected from a catheter into the right seminal vesicle and vas.

This is in all probability the first radiogram taken in this country on the living subject of the seminal vesicle and vas by means of a catheter. The method has become available owing to the genius and determined zeal of Dr. Joseph McCarthy, of New York, and Mr. Reinhold Wappler.

The first invention that made this manipulation feasible was that of the Foroblique telescope which gives a view of the verumontanum and deep urethra from an entirely fresh angle as compared with the older urethroscopes. Even with this telescope catheterisation was not possible until the invention of an ingenious double cannula which holds the catheters and ends in two little spring wheels. The catheters run round these wheels and emerge laterally and then run forward so as to point directly into the entrance of the ejaculatory ducts. The ejaculatory ducts have been catheterised previously in the living subject with other instruments, but the manipulation has been a very difficult one, and in the majority of cases not only unsuccessful but liable to cause damage to the ducts. With McCarthy's instrument the manipulation is not a difficult one to carry out by those accustomed to catheterising ureters, and it does no damage to the delicate structures involved. McCarthy has already carried out these catheterisations in a large number of cases, and is engaged in an intensive study of the living anatomy of the vas and vesicles.

I am indebted to Dr. Malcolm Simpson, of St. Paul's Hospital, for furnishing me with this case, and to Dr. Mather Cordiner and his assistant Mr. W. Mo[illegible] of the same hospital, for taking the radiogram.

I have now catheterised the ejaculatory ducts with this instrument in eight cases, and think that attention should be called to the possibility of the manipulation. Suitable cases need very careful selection, and must be prepared for the [illegible] by a course which includes the passage of large metal bougies and the instillation into the deep urethra of strong silver nitrate. It is hoped that the method will prove useful and be indicated in those who wish to know if their ejaculatory ducts are patent after prolonged attacks of vesiculitis and in those cases of vesiculitis in which it is necessary to know if [illegible] area remains in the vesicle where infected secretion may be shut up and likely to be a source of reinfection at a later date. Also it is hoped that it may be possible to wash out the vesicles by this method and cure chronic cases of vesiculitis.

Nevertheless I feel that after some years' further experience it is likely to be found that disinfection of the vesicles can be more readily acc[illegible] and with less risk of setting up epididymitis by m[illegible] of open vasostomy after the method of Belfield which permits of lavage of the vesicles from above. [illegible] have carried out this method with almost unifo[illegible] success in more than 70 selected cases as described in previous papers.[1]

THE VITAMIN B_2-POTENCY OF COMMERCIAL LIVER EXTRACT.

BY B. C. GUHA, M.SC., PH.D.,
TRAVELLING FELLOW OF THE UNIVERSITY OF CALCUTTA;
(From the Biochemical Laboratory, University of Cambridge)

IN course of a search for a potent source of vitamin B_2, it was found that Eli Lilly's commercial liver extract No. 343 would produce good growth in rats kept on a vitamin B_2-deficient diet in doses as small as 40–60 mg. On the other hand, it is comparatively poor in vitamin B_1, for it produces subnormal growth in B_1-deficient rats in doses of 120 mg. The commercial liver extract, as a raw material for the concentration of vitamin B_2, has thus several advantages over yeast. It is richer in B_2 than yeast and poorer in B_1. It provides a more easily manipulable material. Moreover, nearly all the vitamin B_2 in it can be extracted with cold water.

---

[1] Kidd, F.: THE LANCET, 1923, ii., 213, and 1928, ii., 25; Brit. Jour. Ven. Dis., 1930, vi., 79.

Among the rats which were kept on a vitamin B_2-deficient diet for over nine weeks, a large proportion developed a curious form of depilation. The fur fell off in a manner such that the animals developed a "close-cropped" appearance, without there being any bare patches on the skin. Within four to five days of the feeding of the liver concentrate the fur began to lengthen and soon resumed the normal "lying-down" appearance. A very minor proportion of the animals developed lesions in the feet and paws and near the mouth, and in those that did, these symptoms cleared up very rapidly under administration of the liver extract.

It thus appears that the commercial liver extract, besides being a rich source of the pernicious anæmia factor, is extremely rich in the pellagra-curative factor. It should presumably provide a better material than yeast for the cure of human pellagra.

As it is not yet clear that pellagra is due to a simple deficiency of one factor, it is suggested, in order to have greater clarity in this domain of research, that the factor, which is assayed by means of rat growth tests, be called vitamin B_2, while the factor or factors which are specifically concerned with the cure and prevention of experimental pellagra in rats and which are assayed by means of curative and preventive tests, be called the P–P (pellagra preventive) or the A–P (anti-pellagra) factor. This provisional arrangement would probably prevent some confusion.

MEDICAL SOCIETIES

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY.

AT a meeting of this society, held on April 9th, at Chandos-street, W., the chair was taken by Dr. O. H. WOODCOCK, the President, and Dr. LANGDON BROWN opened a discussion on

Anorexia Nervosa.

He put forward anorexia nervosa as a pathological example of the painful process of detachment of the individual from its parents. The name had been given to the condition in 1873 by Sir Wm. Gull, who had previously described it in 1868 as apepsia hysterica. He had recognised the importance of the mental state and had called attention to the slow pulse- and respiration-rates, the clean tongue, and the incidence in young women between 16 and 21. The prognosis he had regarded as good, saying that there was hope as long as life lasted. Dr. Brown also quoted the graphic descriptions of Gee and Clifford Allbutt, and said that the condition was not uncommon. Anorexia was usually profound and was rationalised on one of three grounds: humanitarian grounds, the desire for slimness, or religious grounds—more often in the rare male cases—allied to a repugnance against all bodily functions. After a time the inability to take food became genuine, owing to atrophy of the digestive organs. The practitioner must always be on the look-out for clever ways of disposing of the food. It might be given to animals, or hidden in curious places such as the piano. Constipation was invariable and should be treated by paraffin and agar, and never by drastic aperients. Amenorrhœa was always present, and the return of the periods was a good sign. Wasting was extreme, and the skin had a rough, dry character. The facies was either resigned or frightened and the nose congested; the cheeks were cyanotic, and the hands cold and blue. The expression was childish for the patient's age.

Patients generally admitted reluctance to grow up, and usually showed undue dependence on the father and hostility to the mother; the latter might be concealed by an exaggerated show of affection, with constant opposition on small points; it might be admitted in the mother's absence, or might be quite frank. Dr. Langdon Brown described the four male cases he had met. One of them had developed tuberculosis and died; this disease was a constant danger to these patients. Another had had a violent antipathy to his mother and to milk in any form: he had been a homosexual. In all cases the trouble had arisen from a perverted attempt at sublimation, and this origin was probably more common than was realised. The protest against swaddling-clothes was more likely to appear when the patient experienced a conflict between the two urges in life. Behind anorexia nervosa sometimes lurked the shadow of dementia præcox, though the subject of anorexia was often extraverted; if introversion occurred in such a case the prognosis was bad.

INFANTILISM.

Keith had remarked that the tendency to carry infantile characteristics into adult life had played a large part in human evolution. But just as this might be a source of strength, so it might prove a weakness. Everyone tended to grow up in patches. The infantile psychical attitude in the psychoneurotic was the manifestation of a characteristic which had a high evolutionary value.

Dr. F. G. CROOKSHANK remarked that the work on this subject had all been done within living memory, and described a fatal case he had seen in 1892. At that time the condition had been commonly supposed to be the result of latent tuberculous infection: no advance had been made on the psychological side. He was quite sure that the cases were much more frequent in certain cultural and religious milieux than in others. They were seen by physicians rather than by psychologists—often only a few days before death. Most cases had had some form of vaccine treatment based on irregularities of the intestinal flora, and many had been in sanatoriums for calcified glands at the hilum. The age-incidence was not a rigid one; refusal of food might occur in various types of mental case. There was, however, a difference in psychology between the adult case and the typical adolescent case as described by Gull. Anorexia nervosa might also be seen in children. In the typical case the individual had long shown signs of negativism and digestive disturbance, the mother having paid special attention to the alimentary tract from an early age. The condition did not break out suddenly; there was alimentary organ inferiority. Possibly marasmus in babies might provide precocious examples.

C. Lasègue had written an important paper in 1873 describing ten cases. He had restricted the age to 15 to 20, and had seen both male and female cases. While appreciating the psychological origin and nexus, he had not gone so far as to suggest investigation of the past. He had mentioned strong emotion and contrariety. Several people had remarked on the importance of the marriage of a younger sister. Dickens had drawn an example in Sarah Crewler, mentioned in "David Copperfield." Most of the cases had been an only child or a rival child. Lasègue had stressed the importance of studying both patient and entourage, as they were Solidaires. He had also pointed out how the patient was "trained" by the environment to produce the symptoms.

Dr. Crookshank's impression was that the fathers of female patients were weak rather than dominating. The mothers who identified with their daughters in this way were not having a satisfactory sexual life and all their libido went to the supervision of the daughter. They were smothering mothers. The children shrank from growing up because they knew that they were incapable of taking their place among their contemporaries, owing to this smothering process; they longed to get out. It was doubtful how far the sexual element entered into these cases; the patients took to masturbation in the later stages, but it was not a primary condition. The purposive character of the manifestations had been recognised by Lasègue, who had divided the progress into three stages. The first was ushered in by some acute complaint—some severe dyspepsia. Then the patient began to say that she could not eat because of the pain; it was important at this stage not to declare that she "ought" to eat, as this drove her into a campaign of hostility, which she conducted with cunning and implacability. She should be treated gently. The second stage was that of systematisation or organisation, where the patient had her scheme mapped out and began to triumph. She suffered no more, led an active life without thirst or amenorrhœa, and ate just what she liked. She would not make the slightest concession, as that would admit caprice, and any insistence only increased her resistance. The third stage was marked by thirst and amenorrhœa, and then the patient became alarmed and would accept treatment if the doctor had been wise during the earlier stages, or would go to another doctor. No patient developed tuberculosis unless she had been discouraged; it had a definite psychological basis.

The refusal to eat might be analogous to the wild flying about of a bird in a room: a primitive behaviour which eventually found the way out. Animals suffered from anorexia nervosa. It might be a revolt against loss of liberty. The greatest psychological force active in these cases was resentment at loss of liberty. The art of treatment lay in managing both patient and mother and in separating them at all costs. Relapses were rare. Anorexia nervosa over 30 was really constructive suicide.

Dr. LANGDON BROWN mentioned two adult cases in married women. One was a remarkable example of the "relentless campaign," and had succeeded in starving herself to death; her husband had denied her the children for which she had longed. The father was often weak—"a darling"—but in some cases he was very well balanced.

The CHAIRMAN mentioned a girl who had nearly died of anorexia nervosa but had recovered after her father's death and become a great traveller.

Dr. JAMES YOUNG said that anorexia nervosa was a profound reaction against authoritarianism, and quoted a case where the patient had recovered but had subsequently developed dementia præcox. An allied condition had been seen in a girl who had had attacks of over-eating, after which she would take an emetic and fast for several days. The father and mother had disagreed and he had left the home when she was six. She had had a terrible time later with a stepmother and younger stepsister, and had begun to fast from the time when she had been wrongly accused of pregnancy. It had been an attempt not to be a woman any longer. J. F. Venables's cases all seemed to arise from fear either of the father or of Jehovah—i.e., fear of sex.

Dr. C. SCHIFF thought that there must be some profound reason for the amenorrhœa. It might be due to some central lesion—some refusal of the whole body—common to it and the anorexia. The condition occurred in decades and in people when the bodily functions were particularly despised. The association with asceticism in history was interesting.

Dr. LANGDON BROWN said that there might be a gonadal hypofunction accounting for the amenorrhœa. The fear of nocturnal emissions after a large evening meal might be the start of anorexia. Sexual suppression was, however, a minor factor.

Dr. CROOKSHANK pointed out that amenorrhœa only appeared at the third stage.

Dr. M. MARCUS described a case under his care. Her improvement had begun from an engagement but had continued although the engagement had been broken. Another girl had admitted annoyance at the engagements of her brother and sister; she had had an adoring father and a nagging mother. A third patient had shown the typical first stage of pain; her mother had swaddled and spoiled her, but the father had now decided to send her away from home.

Dr. J. R. REES asked why older cases were to be regarded as suicidal; was the type different, or was the patient hopeless? He also asked what was the value of symptomatic treatment.

Dr. LANGDON BROWN said that Sir Wm. Gull recommended "the treatment suitable for of unsound mind." Glucose and insulin might useful, but the chief lines were separation from parent, moral suasion, and filling the bowel roughage.

Dr. CROOKSHANK said that the apparent of the plan in adolescence was to achieve independence, and the best way to treat the patient was to hold hopes of that independence. The older cases were against a dead-end and wanted to die. Brud Carter, in his book on hysteria, recognised the psychological basis to an astonishing extent, but he regarded the circumstances as perfect and attemp to break the patient to them, whereas the modern therapist tried to modify the circumstances.

Dr. G. GORDON described mild cases among men over 30 in suicidal wards. He thought that they were all patients who were in hospital under protest. Their refusal of food was an anti-authority protest, and he had treated it by trying to get them to make friends with the hospital and realise the amount of liberty allowed. The condition might arise from protest against any authority—even a Government department.

Dr. S. D. ISAACS described a case in a married woman who had intensely disliked sexual intercourse, and had began to refuse food after procuring an abortion. Some 20 years later she had developed septic teeth, with complete disorganisation of the digestive tract. She had always shown intense obstinacy.

Dr. E. L. TAYLOR described an adult case occurring after the fifth pregnancy, which had been complicated by threatened eclampsia. The history showed tragic domination and dislike by the mother, cruelty in childhood, seduction by her first employer, and repeated pregnancies. She could not face the future and was refusing food, although protesting that she must get better to look after the children.

Dr. **BEVAN BROWN** doubted whether the condition was always a protest against authority. He had known cases where the first reaction was a feeling of being superfluous and unloved; later the mother tried to make up for her failings and became "smothering." The degree of lack of insight might approach that of dementia præcox. Patients often vomited if they ate or were forced to eat a little more than they thought correct.

Dr. **CROOKSHANK** said that the feeling of not being wanted was common to almost all neuroses; the protest against authority was more peculiar to anorexia nervosa.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this society on April 4th, with Mr. H. **NETHERSOLE FLETCHER**, the President, in the chair, a paper on

Acute Intestinal Obstruction

was read by Mr. J. R. H. **TURTON**. He began by presenting statistics of 300 cases of acute obstruction admitted into the Royal Sussex County Hospital during the past ten years—96 of these being cases of obstruction from intra-abdominal causes, and 204 cases of strangulated hernia. The total mortality proved to be about 30 per cent.—52 per cent. for the internal cases and 20 per cent. for the hernias. It was found that the average age of the former group was 49 and of the latter 59 years, and the duration of acute symptoms before hospital admission was 2 days 20 hours, and 1 day 21 hours respectively. The highest mortality-rates were among cases of internal hernia, carcinoma of the colon, and multiple adhesions, while the lowest rates were among cases of obstruction caused by a single band or by impacted gall-stones. The average duration of acute symptoms before admission differed widely among the different classes of obstruction, and the different mortality-rates in the several classes could not be attributed to the different periods of delay in their diagnosis. Among the strangulated hernias, the mortality was 22 per cent. for the inguinal (91 cases), 12 for the femoral (90 cases), 44 per cent. for the umbilical (16 cases), and 43 per cent. for the ventral (7 cases). The mortality among the femoral cases in the female was especially low—64 cases with four deaths. Of these four cases, two were late ones, each having been strangulated six days and necessitating resection of the bowel for gangrene; one was a case of toxic goitre which proved fatal suddenly three days after operation; and the fourth a case of chronic nephritis in which the cause of death was suppression of urine. Fæculent vomiting was present in 24 per cent. of the internal cases (mortality 56 per cent.), and in 16 per cent. of the hernia cases (mortality 50 per cent.). Of the 40 cases in which obstruction was due to adhesions, 21 had undergone previous abdominal operation, and in all of these the obstruction was a direct sequel.

Mr. F. E. **FEILDEN** showed a case of intestinal obstruction due to a malignant adenomatous polyp occupying the lumen of the jejunum.

LIVERPOOL MEDICAL INSTITUTION AND MANCHESTER MEDICAL SOCIETY.

A JOINT meeting of these societies was held at Liverpool on March 5th, when Mr. **GEOFFREY JEFFERSON** read a paper on the

Surgery of the Pituitary Body.

After referring to the two main groups of pituitary dysfunction, he spoke of the symptoms once regarded as of pituitary origin but which now seemed to be tuberal. Striking hypopituitary pictures might be induced, he said, by tumours at a distance—notably by those in the cerebellum with retention dilatation of the third ventricle and damage to the hypothalamus. The acromegalic group of cases were no longer the most important clinically for they represented the minority of pituitary enlargements. In this disease the glandular change was not a true tumour, but a hypertrophy with toxic secretion. The commoner chromophobe adenoma appeared to be a true tumour and produced its effects by interfering with the normal pituitary secretions. Mr. Jefferson thought that too much attention was paid in teaching and discussion to the somatic effects of pituitary tumours. These required some time for their development, and an adenoma might become large enough to cause blindness by compression of the optic nerves before any gross signs of general body change made their appearance. He thought this fact ought to be more widely known because the diagnosis of pituitary tumour was often very considerably delayed or missed altogether because of the absence of those signs which the clinician had been taught to expect in pituitary lesions. Conversely it seemed to him that the most obvious pictures of hypopituitarism were given by persons who had no pituitary tumour at all. In these some infection or acute illness seemed to have damaged the gland. At all events it was unwise to diagnose tumour on somatic changes alone.

Mr. Jefferson said that at operation he was using the trans-frontal route as worked out by Frazier and Sargent, but he thought that for the moderate-sized cyst the trans-sphenoidal route was safer. The difficulty was to know beforehand which was the better route for any given case. The risks of post-operative hyperthermia were certainly less by the nasal route, but it was an unsatisfactory approach for the more solid tumours.

Sanocrysin.

Dr. H. T. **ASHBY** read a paper on the Treatment of Pulmonary Tuberculosis in Children by Sanocrysin. This drug, which was introduced in 1925, was not received favourably, he said, when first tried in this country, the reason being that it was used in unsuitable cases and given in too large doses. As time went on its value as an adjuvant was being more widely recognised. It was best used in the so-called exudative type, where there was a fresh area of spreading disease, and was unsuitable for abdominal or renal tuberculosis. Sanocrysin was well tolerated by children and was given them by intramuscular injection of a 3 per cent. solution, the initial dose being 0·01 g. A course consisted of 10 to 12 injections with a maximum dose of 0·5 g. With these amounts the children had been entirely free from undesirable symptoms and most had shown an increase in weight and steady improvement of symptoms. The dangers to watch for were diarrhœa and albuminuria. The results, especially in severe cases of bad prognosis, were often such as to encourage a prolonged trial of sanocrysin combined with the usual methods of treatment. It was not a specific but it often helped to shorten the illness.

Stone in the Ureter.

Mr. J. B. MACALPINE said that large stones in the ureter could be diagnosed by X rays alone, but the presence of small ones must be confirmed by cystoscopy, since there were many radiological pitfalls. A stone might be invisible because of its small size or permeability to X rays, and there were many shadow-casting objects round about the ureter which might cause confusion. The speaker showed plates in which an opaque bougie acted as a pointer, its tip abutting on the stone, or passed close to the stone and demonstrated the close apposition of the two. Shifts of the X ray tube and re-exposure would, he said, make this relationship more convincing, or stereoscopy might be employed. Pyelography, by outlining the ureter, demonstrated that the shadow was within its lumen. Where a stone was transparent it might be seen in the pyelogram as an area of diminished opacity.

REVIEWS AND NOTICES OF BOOKS

Zehn Jahre Forschung auf dem Physikalisch-medizinischen Grenzgebiet.

Edited by Dr. FRIEDRICH DESSAUER, Director of the Institute for the Physical Elements of Medicine, University of Frankfurt-am-Main. Leipzig: Georg Thieme. 1931. Pp. 403. M.36.

THE valuable work carried out at the Institute for the physical basis of medicine, in Frankfurt, is already known in this country through the publications of papers and extracts in English medical journals, but we owe gratitude to Prof. Dessauer, the Medical Director of the Institute, for publishing in book form this series of 15 original researches in honour of the tenth anniversary of the foundation of the Institute. The Frankfurt Institute was founded at a time when it seemed almost impossible to raise the necessary funds for an institution which promised no immediate returns for an investment. It arose in answer to a conviction, which has been gaining more and more ground in medical and scientific circles, that physics could become as useful to medicine as chemistry had already become to biology. The lack of trained workers possessing a sufficient knowledge of medicine and also of physics in its more recent developments was painfully obvious. The Institute was designed to train the workers it required, and by its affiliation to the faculties of medicine and science it facilitated the coöperation of experienced clinician with expert physicist. We are told by Dr. Dessauer that the work chosen for publication in the present volume in no way represents the total output of work done at the Institute, and when we remember that the Institute has been in constant financial difficulties almost since its foundation, owing to the loss of its original endowment, and that it has had to be self-supporting by the manufacture of scientific instruments and the organisation of classes and consultations, we must admire the ingenuity of the directors and the devotion of the medical and scientific staff which enabled them to do such good work under difficult circumstances.

Of the various researches reported in this volume the most important one, to which most space has been allocated, is a study of the effect of exposure of normal subjects and selected patients to an atmosphere carrying a measured number of either positive or negative ions. This study was suggested by observations on atmospheric susceptibilities of various individuals, by the symptoms observed during changes of altitude and exposure to various winds, by mountain and Föhn-sickness, and by the dependence of rheumatic manifestations on weather and climate. An underlying physical factor was suspected. The research which is here published makes it abundantly clear that the number, size, and positive or negative charge of the ions in the inspired air are among the factors determining the effect of climatic conditions on the welfare of the individual. Inhalation of air containing negatively charged particles was found to cause a fall of blood pressure in patients with raised blood pressure, the fall being often marked and always accompanied by relief of subjective symptoms. In normal subjects a *feeling of freshness* and absence of fatigue and in cases of subacute and chronic rheumatism exacerbations of symptoms and sometimes of local signs, associated with subsequent improvement in a certain number of cases was also noted. Inhalation of air carrying measured quantities of positively charged ions caused untoward symptoms in cases with raised blood pressure, and often marked distress associated with a further rise in blood pressure. Other researches include: studies on the fundamental biological reactions of radiation and on detection and measurement of the mitogenetic rays of Gurwitsch; measurements of the transmission of radiation through the skin and tissues and of intensity distribution in irradiated media; electro-magnetic measurements for study of the superficial strata of the soil; and many investigations of new and old apparatus for measurement of radiations of various wave-lengths. An index of the investigations published by the Institute since 1920 occupies 10 pages of small print, a remarkable output of work.

Modern Methods of Treatment.

Fourth edition. By LOGAN CLENDENING, M.D. London: Henry Kimpton. 1929. Pp. 819. 42*s*.

Dr. Clendening's manual of treatment was first written to provide an outline of all the methods of treatment used in medicine, and in this—the fourth—edition his intention has not been changed. He has aimed at supplying details, not only of dietetic and drug therapy, but also of such procedures as blood transfusion, hydrotherapy, artificial pneumothorax, and the like; so that the reader might be enabled to carry out the technique without actually having ever seen the treatment applied. The first section of the book is taken up with drugs and dietetics; the latter section is particularly full, and many of the practical instructions given are not easily found in other books. The chapters on Infant Feeding, written by Dr. Cowherd, contain much useful information. The action of drugs is considered first from a pharmacological standpoint; their application in particular diseases is discussed in the second part of the book. Chapters are included on medical gymnastics and massage, exercise, electrotherapeutics, radiotherapy, and other physical lines of treatment. For the most part descriptions are concise and brief.

On the whole, the chapters are well balanced, and there are few omissions. The book is more than a mere work of reference. It is written in a direct and simple manner, with some excellent quotations from original papers, and makes interesting and, in places, entertaining reading. There are numerous illustrations and diagrams, some of which are of an elementary nature and might have been omitted, and a few references are given at the end of individual chapters.

Dr. Clendening is to be congratulated upon the large amount of valuable information which he has collected. The index is excellent. This fourth edition follows closely upon the third. Among the new methods of treatment included are desiccated swine stomach in pernicious anæmia, the parathyroids, and Calmette's B C G vaccine.

Diseases of the Thyroid Gland.

By NELLIS BARNES FOSTER, Associate Professor of Medicine, Cornell University Medical College; with a section on *Malignant Growths* by EUGENE H. POOL, Attending Surgeon, New York Hospital. London: Baillière, Tindall and Cox. 1930. Pp. 174. 6*s.*

INTO the short space of 170 odd pages Prof. Foster has condensed all the important facts which the student should know about thyroid disease, or which the general practitioner will require for the diagnosis and treatment of his cases. Chapters are included on thyroiditis, goitre, tuberculosis and syphilis of the thyroid, athyrosis and hypothyrosis, and exophthalmic goitre. Prof. Pool, of Columbia University, has collaborated in the final chapter on Malignant Growths of the Thyroid. There is little to criticise in the subject matter of the book, and its arrangement and size are thoroughly satisfactory. It should find as wide an acceptance in this country as it has already done in America.

The Complete Law of Housing.

By H. A. HILL, B.A., Barrister-at-law. London: Butterworth and Co., Ltd. 1931. Pp. lviii. + 394. 25*s.*

Mr. Hill's "Complete Law of Housing" contains the text of the 1930 Act and the unrepealed parts of earlier Housing Acts. The introduction tells the history of the legislation and includes a sensible analysis of the slum problem. There is a reasonably complete appendix of Statutory Rules and Orders and other documents. The Treasury Minute which fixed the rate of interest under Section 90 (6) of the 1925 Act is not cited; perhaps it was not deemed of general importance. These regulations and orders soon fall out of date; already, since the book went to press, the Ministry of Health (Rate of Interest) Amendment Order of last April has been superseded. The annotations to the statutes will be found serviceable. Is it accurate to say that the words "clerk or" in Subsection (4) of Section 69 of the 1909 Act were repealed by the 1925 Act? Parliament doubtless meant this to happen, but muddled the reference. On page 28 Mr. Hill prints Section 11 of the Housing (Additional Powers) Act, 1919, as though it explained "local authority" in the only other section printed above it. Is not this misleading? Section 11 was required for various other sections now dead; can it modify the local authorities in the 1916 Act to which Section 8 refers? There is a useful note on page 190 where the editor calls attention to an ambiguity in Section 9 of the 1930 Act; his interpretation seems to differ from that of the department. The views of the joint author of "Hill and Oliver's Local Government Act, 1929" are entitled to consideration. His new book will help those to whom the impact of the 1930 Act upon the 1925 Act (as contrived by Section 63 of the recent statute) is not too simple a matter.

Warren's Handbook of Anatomy.

From Original Dissections by JOHN WARREN, M.D., late Associate Professor of Anatomy, Harvard Medical School. Text by ROBERT M. GREEN, M.D., Assistant Professor of Applied Anatomy at Harvard Medical School. Published by Harvard University Press. London: Humphrey Milford, Oxford University Press. 1930. Pp. 384. £3 3*s.*

THIS volume has been compiled by the Harvard colleagues of the late Prof. Warren, in order to complete the work on which he had been engaged for several years before his death. It has been built up round the dissections and drawings left by him to the Anatomy Department in which he worked. The drawings, made for the most part under Prof. Warren's supervision, are from the pencil of Mr. H. F. Aitken, and form an outstanding feature, being beautiful reproductions. The text is clear and simple. The first year's course in anatomy, which the book is said to meet, is not the same as the first year's anatomical work in England, so that it is no reflection on this book if we say that it does not, in our opinion, go far enough in its scope to take the place of any of the current text-books or manuals in use in this country. The same line of criticism might be applied to it from the clinical side. Nevertheless, the volume is a pleasing one, and is very well produced.

Developmental Anatomy.

A Text-book and Laboratory Manual of Embryology. Second edition. By LESLIE BRAINERD AREY, Robert Laughlin Rea Professor of Anatomy, Northwestern University. London: W. B. Saunders Co., Ltd. 1930. Pp. 563. 27*s.* 6*d.*

THE first edition of this book, which was an elaboration of Prentiss and Arey's manual, was reprinted several times, and was one of the best of what might be termed "formal" embryological books. This issue, however, is much more than that. The recognition and inclusion of work previously ignored, and the addition of reference lists to the chapters, have given it a value much higher than it possessed before. Moreover the careful re-writing of the subject matter throughout has, with the changes mentioned, lifted the work to the rank of a book of reference to be used by others than those who are professedly students. We welcome its appearance.

Tobacco.

By W. L. MENDENHALL, M.D. Harvard University Press. 1930. Pp. 69. 4*s.* 6*d.*

THIS is one of the "Harvard Health Talks" and is given by the professor of pharmacology in the Boston University School of Medicine. It is a very reasonable review of the facts about tobacco-smoking as far as they are known. It is an expensive habit, bad for the pharynx, duodenum, and heart and, in the young, *associated with loafing and inferior scholarship.* Evils are possible but not certain, and everyone must make up his own mind whether the habit is worth while. The author would perhaps have cleared the discussion a little more if he had distinguished between the effects of tobacco on young persons and on those whose bodies are beginning to be particular about the treatment they receive.

X Ray Technology.

The Production, Measurement and Applications of X Rays. By H. M. TERRILL, Ph.D., Associate in Physics, Institute of Cancer Research; and C. T. ULREY, Ph.D., Research Physicist, Westinghouse Lamp Company. London: Chapman and Hall. Pp. 256. 21*s.*

THE authors state that it has been their aim to lay stress upon the "practical rather than the theoretical aspect of X ray measurements." They are to be congratulated on the result. Their great experience in this field has enabled them to produce a book which should prove valuable to the radiologist and physicist alike. In 11 chapters they deal clearly and concisely with X ray tubes and their practical operation, measurements of current, voltage, ionisation, total energy and wave-length, X ray analysis of crystals, radiography, and biological measurements. While the information given is of the practical kind required by every X ray worker, the theoretical basis of the measurements is never lost sight of. The printing, paper, and illustrations are all excellent.

The Spiritual Life Viewed from a Scientific Standpoint.

By T. STACEY WILSON, M.D., F.R.C.P. Birmingham: Cornish Bros. 1930. Pp. 50. 1*s.*

Dr. Wilson hardly looks at the spiritual life from the point of view of a scientific man. He does what several others have done in recent years and writes in a very helpful way to affirm his experience that the scientific training and life of a medical man is in no way incompatible with the enjoyment of spiritual values to the full. To love one another is man's highest achievement. This cannot be proved by any process of reasoning which can be called a scientific argument; if we believe it to be true, it is on the strength of experiences such as Dr. Wilson summarises.

The Papyrus Ebers.

Translated from the German version. By CYRIL P. BRYAN, M.B., B.Ch., B.A.O., Demonstrator in Anatomy, University College, London. With an Introduction by G. ELLIOT SMITH, M.D., D.Sc., Litt.D., F.R.C.P., F.R.S., Professor of Anatomy, University College, London. London: Geoffrey Bles. 1930. Pp. 167. 10*s.* 6*d.*

THIS is the first rendering in the English language of what the translator firmly claims to be the most ancient book in the world. It is certainly the longest and most famous of the documents relating to the ancient practice of medicine. Prof. Elliot Smith, in his delightful introduction, deplores the assumption even by the most learned historians that the history of medicine began with the Greeks, and that before the time of Hippocrates there was little or nothing that can be called a science of medicine. And here is a book written about 1500 B.C. which shows that there was at that time considerable knowledge of the diagnosis and treatment of disease. Prescriptions for different diseases, specifying the name of the drugs, many of which are in common use at the present day, the dosage of each, and the method of administration, are to be found there; also some observations on diagnosis and on the surgical treatment of wounds and suppurating sores, interspersed, of course, with spells and incantations. Dr. Bryan deserves congratulation for his energy and skill in providing this excellent translation and commentary. Prof. Elliot Smith's hopes that it may stimulate students of folk-lore and archæology, of herbals and theology, to be alert for clues which will provide information for the identification of diseases and drugs, and for an illumination of the principles underlying the ancient physician's methods of practice.

Sixty Centuries of Health and Physick.

By S. G. BLAXLAND STUBBS and E. W. BLIGH. London: Sampson Low, Marston and Co., Ltd. 1931. Pp. 253. 15*s.*

IN a review of this book published in THE LANCET of April 4th (p. 762) we regret that the title was incorrectly given.

British Journal of Children's Diseases.

IN the January-March issue (Vol. XXVIII.) Dr. Leopold Mandel distinguishes five types of enuretics, viz.: (1) Those children in whom some palpable physical irritating stimuli exist, such as worms, over-distension of the bladder, or cystitis. In such cases the treatment is obvious. (2) The hypersensitive or neuropathic type, which responds to dietetic and medicinal measures combined with readjustment of environment and gentle re-education. (3) The so-called psychopathic child, in whom the enuresis is more a behaviour complex, and the treatment required is for the most part psychological. (4) Endocrine dysharmony, particularly hypothyroidism leading to a loss of inhibition. In such cases small doses of thyroid with pituitrin as an adjuvant are indicated. (5) The debilitated child, often convalescent from some illness, for whom general tonic treatment is indicated. In all types atropine or belladonna is the specific drug of choice.—Dr. F. Parkes Weber reports a case of Complete Mindlessness (Lowest Degree of Idiocy) and Cerebral (Cortical) Diplegia after Status Convulsivus Associated with Ether Anæsthesia, and gives references to other cases of severe and dangerous convulsions in children following ether anæsthesia or alcoholic drinks.—In a paper entitled Measles Encephalitis: Two Fatal Cases, Dr. E. C. Benn records cases in a girl aged 8 and a boy aged 5 years. The first case was unusual in that acute encephalitis occurred on the reputed third day of illness within 24 hours of the appearance of the rash after an apparently normal onset of the disease. Death took place within 25 hours of the onset of cerebral symptoms. Both cases showed signs of severe and widespread cerebral damage, and the prognosis was hopeless from the first. Typical histological lesions were found in the brain in each case.—Dr. John Craig and Dr. Alexander Lyall report a Case of Calcinosis Universalis and a Suggested Method of Treatment. The patient was a girl aged 5 years, in whom after all other treatment had failed, the administration of di-sodium phosphate, first in half drachm doses thrice daily, and then in one drachm doses four times a day led to rapid disappearance of the calcinosis.—In a Note on Congenital Developmental Diseases, Dr. Parkes Weber emphasises the need of an atlas showing, by means of photographs, skiagrams, sketches, and diagrams, all the macroscopic structural features met with in the various hitherto recorded types and combinations of types.—The abstracts from current literature are devoted to tuberculosis.

THE LANCET.

LONDON: SATURDAY, APRIL 18, 1931.

HUNGER PAIN.

OF all the symptoms associated with disorder of the stomach hunger pain is the most important, for it at once arouses suspicion of an organic lesion close to the pylorus. This fact, whose enunciation we owe first and foremost to Lord MOYNIHAN, has made it possible during the last 30 years to diagnose and treat peptic ulcer with precision, whereas previously the condition remained undetected among the congregation of symptom-complexes known as dyspepsia. It was long supposed that hunger pain was the expression of an excess of free hydrochloric acid in the stomach, and this was the dogmatic teaching of authorities such as C. A. EWALD, F. RIEGEL, and S. and V. S. FENWICK. Their opinion was almost universally accepted, and is indeed the basis for the recognition of "hyperchlorhydria," which, on insufficient grounds, is regarded by many as a disease. More recently clinicians have been largely converted to the belief that excess of acid is only an indirect cause of the pain in that it sets up painful contractions of the gastric or pyloric muscle. Now, however, a small but influential body of opinion goes further and has come to hold that the acid factor has little if anything to do with the genesis of hunger pain, considering that hypertonus of the stomach and pylorospasm alone are causes of pain, and may be present without any increase in the acidity of the gastric contents. Of workers in this country, T. I. BENNETT, J. A. RYLE, A. F. HURST, and I. T. VENABLES, may be quoted as among the more prominent exponents of this view.

A valuable contribution to the mechanics of hunger pain has just been published by OLINE CHRISTENSEN.[1] Like A. J. CARLSON and his pupils she has followed the method of W. BOLDYREFF, which, in addition to gastric analysis and radiography, consists in introducing a balloon tube into the stomach so that a continuous record of gastric tonus and movement can be obtained. By these means she has collected a large series of observations both of the normal and of various pathological conditions. The investigation of normal subjects confirms the existence of periods of vigorous contraction alternating with almost complete rest. The presence of a sufficient amount of gastric contents, either in the form of food or of gastric secretion alone, produces a change in the contraction curve, weaker contractions replacing the previous vigorous ones. In some normal persons 200 c.cm. of water is enough to cause this change; but in the majority a larger amount of water is required. A food which promotes vigorous gastric secretion is the most effective in diminishing the fasting contractions; while a mixture of egg and milk was found to be the substance best calculated to produce gastric rest. Examination of patients suffering from various diseases reveals that typical hunger pains are always associated with vigorous contractions of the stomach when it is empty or very nearly empty, but such contractions are not necessarily greater in amplitude than those previously observed when larger amounts of food were in the stomach. The relief of hunger pain is due to the reduction of such contractions which occurs in the presence of an adequate gastric content. Titration of samples of the gastric contents shows that the concentration of free hydrochloric acid bears no relation to the vigour of the painful contractions in such cases. As in her purely physiological observations, CHRISTENSEN noted that egg and milk was the food which most readily caused relative gastric rest and an abolition of hunger pain.

Much of this new work is a repetition of CARLSON'S classical observations, but other parts form an ample and scientific corroboration of the opinion long expressed by some of the physicians studying this particular subject. Actually it is of high importance because it lays stress on the extreme utility of rest in the treatment of gastric disorders. W. C. ALVAREZ has written :—

> "One of the lessons to be learnt by the clinician from the work on hunger contractions is that he cannot put the stomach at rest simply by withholding food. Actually, in the presence of an ulcer, the powerful hunger contractions are much more disturbing, and probably more harmful to the patient, than are the waves that course over the lower end of the stomach during the periods of digestion; and certainly, one of the easiest ways in which these patients can be kept comfortable, is by giving them something to eat every two hours."

The value of alkalis in the treatment of gastric ulcer has been emphasised, and probably over-emphasised, during the last decade. While an ulcer bathed in strong gastric juice must necessarily be in a bad medium for healing, it is clear that rest is the all-important factor, as HURST, BENNETT, RYLE, and others have long insisted. Comprehension of the mechanism of hunger pain is necessary before one can understand how gastric rest should be sought and attained.

EARLY MAN.

Sir ARTHUR KEITH, the Conservator of the Museum and Hunterian Professor at the Royal College of Surgeons of England, has added an important volume to his well-known treatise, The Antiquity of Man. This made an original appearance some 15 years ago, and ten years later was reissued in two volumes, the expansion registering the great accession to our knowledge of ancient man which occurred between 1915 and 1925. These volumes were themselves published in revision four years later, but such has been the rate of advance during the last two years that a new book has been necessitated containing a record of the more recent discoveries and analysing their bearing upon the problems of man's evolution.[1]

---

[1] Pathophysiology of Hunger Pains. By Oline Christensen. Collected papers from the Medical University Clinic B. Edited by Knud Faber. Copenhagen. 1931.

The earlier part, about a quarter, of the new book, is concerned with the discovery of the Taungs skull near Kimberley in South Africa, which more forcibly than any other event in palæontology propounds the question—*what is a man and what is an ape?* The intensive knowledge which led Prof. DART of Johannesburg, to whom the Taungs skull was handed by Dr. R. B. YOUNG after exhumation in a quarry near the Harts River, to the decision that he had come into possession of the skull of a child, *about 5 years old, and belonging* to the basal ancestry of the human stock is set out; and Sir ARTHUR KEITH's opinion as to the exact place in an infinitely ancient pedigree is also given. The views of these learned men do not coincide, but the clearness of detail and closeness of reasoning associated with the very popular forms of detective fiction are employed in the telling, and, in consonance with this type of narrative we are left, at the stage which the story has reached, with alternative solutions. Prof. DART conceives of the Australopithecus (so he has christened the little person) as owing descent to the main human stem low down in the miocene period; while Sir ARTHUR KEITH, modernising the ancestry by some 200,000 years according to the modified time scale which he employs, would assign descent to the anthropoid stem at the juncture of the miocene with the pliocene period. To put the diverging theories briefly, while Prof. DART considers that Australopithecus derives almost from the point where the human and anthropoid stems would seem to divide, Sir ARTHUR KEITH elevates the child to a place fairly high up the anthropoid stem, on the way to becoming a gorilla or a chimpanzee. Sir ARTHUR KEITH finds the geological evidence not to agree with any attribution of Australopithecus to a miocene date, finding little or nothing to support the view that we have here a representative of a prehuman stage in man's ancestry. We are compelled, he thinks, to attribute the Taungs skull to a geological period when man was already in existence, while the manifestations of certain humanoid characters are merely reminders of a common inheritance of the great anthropoids and man at a period too far behind us for contemplation.

While the Taungs discovery is thus prominently put before us as the chief event of the period dealt with, in the rest of the book it may almost be said that the rest of the world is brought into association with archæological research. We hear of ancient men, and their place in the great pedigree, whose remnants have been unearthed in other parts of Africa, in Palestine, Egypt, China, Spain, Italy, and Russia, in America, Scotland, Ireland, and England, the story ending with the exhumation of the fossil woman reclining in the heart of the City of London, beneath Lloyd's and within a few yards of the Mansion House and London Bridge. *The skull of this skeleton,* which is now in the Museum of University College, London, was examined by Prof. ELLIOT SMITH, and the geological evidence relied upon to confirm its antiquity is given us in great detail. By anatomical analysis the conclusion is reached that the human *skull found under the foundations of* Lloyd's building represents a modification of the Piltdown man, whose period coincides with the pliocene and earliest pleistocene deposits. The assumption is that the London lady had a Piltdown skull, modified through the influences of a long period *of time, and the significance of this theory* is that the objections to placing the Piltdown type in ' direct line of the ancestry of modern man, because of certain simian characters, are felt to be less weighty; evidence is accumulating, as Sir ARTHUR KEITH points out, that structural changes may occur in *groups of humanity long after* their separation from a common ancestor, and that "parallelism" must be accepted as having been a factor in the evolution of human races. So the Piltdown man may turn out to be the ancestor so long searched for; and, with due caution, Sir ARTHUR KEITH takes this view.

THE TUBERCULIN REACTION.

THOUGH tuberculin has been employed fo diagnostic purposes for more than 20 years, nc much of fundamental importance has been a to KOCH's original harvest of discovery, and understanding of the action of tuberculin is far from complete. Knowledge of its chemis is gradually growing. KOCH showed in 1891 by precipitation with alcohol it was possible *concentrate the essential active principle* which when injected into tuberculous animals, pro characteristic symptoms ending in death, the well-known intense congestion of liver, and tuberculous foci seen at autopsy. D the past few years SEIBERT, LONG and M in America, and LAIDLAW and TYTLER, in E have prepared crystalline "tuberculo-protein and the specific "carbohydrate gum." F results obtained with these and Miss SEIBERT latest fractions[1] produced by salt precipitati and hydrolysis, we may conclude broadly that the protein moiety is predominantly associated with "tuberculin," lethal on injection into tuberculous animals, and also causing intrac reactions—though DORSET is of opinion that lethal and the skin-excitant principles are different —while the carbohydrate part is not itself toxic but gives a precipitate in the test-tube with the serum of a tuberculous animal or one injected with large quantities of dead tubercle bacilli. What part is played by the tuberculo-protein or the carbohydrate in the production of the symptoms of tuberculous infection or of immunity after recovery is not yet clear. KOCH showed that an animal, once infected, responded to a second injection of living or dead bacilli by an intense inflammatory reaction. This increased sensitivity of the cells of the infected animal or "allergy" has been considered responsible for most or all of the febrile phenomena of the disease and the various tuberculin reactions. But useful as the expression "allergy" is, it does not here carry us far. We know that the tuberculous animal can be desensitised. The tale runs that the tortuous cattle-dealer will send a man to accompany his prize cattle to South America, with instructions to inject them periodically with tuberculin so that the infected ones will, on arrival, pass the subcutaneous examination with honours. No simple interpretation of this "doping" is to hand. The hypothesis (Giessinger and others) that there is a circulating antibody in the infected animal which causes the subcutaneous or intradermic reaction will not suffice, for we cannot readily demonstrate an antibody by passive transference to other animals. Nor is there any unanimity about "immunity" in tuberculosis. Some state that an adult once positive to skin test remains always positive. Pottenger, on the one hand, believes that the sensitivity of the cells decreases with the healing of the tuberculosis; others hold that it increases.

[1] New Discoveries Relating to the Antiquity of Man. By Sir Arthur Keith, F.R.S. London: Williams and Norgate, Ltd. 1931. Pp. 512. £1 1s. net.

[1] Seibert, F. B., and Munday, B.: Amer. Rev. Tuberc., 1931, xxiii., 23.

When we compare the views of the veterinary surgeon and the laboratory worker we find a refreshing measure of agreement. Tuberculins made from human and bovine bacilli apparently contain the same tuberculo-protein and carbohydrate, and will equally detect infection with either bacillus; the tuberculin reaction indicates active infection with the tubercle bacillus; the larger the dose used, the earlier after infection can one elicit the tuberculin reaction; in the final stages of the disease tuberculin may produce no reaction. Both groups of inquirers use the subcutaneous method but both favour intradermic injection, veterinarians injecting into the caudal fold—a method which gave satisfaction in some millions of tests in America—or adopting the convenient "repeat" injection of the Douglas-Buxton method favoured in England. There is no satisfactory evidence that workers in the past used tuberculins of comparable potency. The Therapeutic Substances Act now requires a potency equal to that of the International Standard Tuberculin, which is based on the original German standard. Given tuberculin of standard potency, the modern clinician tends to use the intradermic Mantoux test in preference to the von Pirquet, in which the precise amount of tuberculin absorbed cannot be measured, or the subcutaneous test which may cause a severe reaction and activate a dormant lesion. The clinical reports, obtained mainly by the Mantoux test, show considerable agreement, though there are still many gaps in our knowledge. It seems fairly clear that we all commence life with a negative reaction, but most have become positive when adult life is reached—we have passed through the fire of infection and those who have not succumbed have developed a relative immunity. If we are still negative, we cannot face exposure without risk. Heimbeck[2] reports that, though only 208 of 397 hospital nurses showed on entry a negative reaction, this group provided 40 of the 43 cases of tuberculosis which developed during the three years' course in hospital.

Dilutions of one hundred-fold or less are used in the intradermic test, the volume injected being 0·1 c.cm.; possibly thousand-fold will eventually be found the most useful routine dilution. Moncrieff, Schlesinger and D'Arcy Hart, examining London children, found the test of great clinical value, though not infallible. W. F. Gaisford has set out his experience in our own columns recently.[3] A negative test up to about the age of 8 is strong evidence against active infection, while a positive reaction equally strongly indicates it. Most authorities would agree with these workers, but after childhood the light becomes less clear. A convenient figure to remember is that at the age of 7 a positive reaction to a thousand-fold dilution of tuberculin indicates a five-to-one chance that the child has an active infection, while at 14 the chance is about even. Blair and Galland[4] propose to get further evidence by using, at one test, dilutions ranging down to one in ten million, and endeavour to fix a "threshold" dilution for various ages, a reaction to which shall indicate active infection. It is doubtful if our knowledge of to-day is precise enough in every population to make this method of test of decisive value to the clinician. We do know that, in the laboratory animal, as the infection progresses after inoculation of live bacilli, the animal will yield positive reactions to more and more dilute tuberculin. It is reasonable to suppose that a series of quantitative observations on the same tuberculous patients at intervals would show whether the average patient obeys the same law. Cummins and Lobban[5] find that the sensitivity remains high or even increases in tuberculosis running a benign course or going on to permanent quiescence. Many clinicians will feel that here is an opportunity of securing data of value to the perplexed practitioner. Could not some authority such as the Medical Research Council or the British Medical Association use its efficient organisation to coördinate work at present in progress and arrange for a large team research, not forgetting a trained statistician?

Royal Sanitary Institute.—The forty-second congress of this institute will be held at Glasgow from July 4th to 11th under the presidency of Sir Henry Mechan. The sectional presidents include Dr. J. Parlane Kinloch (preventive medicine), Dame Louise McIlroy (maternity, child welfare, and school hygiene), Sir David Munro (hygiene in industry), and Dr. J. R. Currie (conference of medical officers of health). On July 10th Major Walter Elliot, M.P., will deliver the congress lecture on A Continuous Health Policy, and on the following day there will be excursions by steamer or motor in the neighbourhood. The offices of the Institute are at 90, Buckingham Palace-road, London, S.W.1.

ANNOTATIONS

MYOCARDIAL DISTRESS.

THE problem of the underlying cause of angina pectoris has long puzzled both clinical observers and pathologists, the two most popular views being those championed by James Mackenzie and Clifford Allbutt. The former regarded angina as an indication of myocardial exhaustion, while the latter found its origin in a lesion of the aorta. Mackenzie's view received encouragement from the clinical recognition of the syndrome of coronary thrombosis; here was a disease with a clear-cut pathological picture, associated with severe anginal pain. The pain may differ in the length of its duration and in its severity from that of angina pectoris, but its site, character, and associated phenomena are identical. Recently Parkinson and Bedford[1] brought forward important evidence that the pain of angina, like the pain of infarction, is due to ischæmia of cardiac muscle, and work on similar lines is now reported by Wood, Wolferth, and Livezey.[2] In the cases of angina pectoris studied the attack was induced by exertion, but the possible influence of this on the electrocardiogram was excluded by controls. Half the patients showed —as in Parkinson and Bedford's five cases—changes in the ventricular complex of their electrocardiograms during the attack and these changes disappeared after the pain had passed off. Admittedly every case did not show this phenomenon, nor was there any correlation between the severity of the attack and the amount of alteration of the electrocardiogram; moreover, cases of coronary thrombosis have been reported which showed no electrocardiographic changes and others which suffered no anginal pain. To test their theory further, Wood and his colleagues investigated the effect on the electrocardiogram of cats and dogs of a temporary occlusion of part of the coronary circulation. They found that by this means they were able to produce changes in the electrocardiograms very similar to those observed in patients during an attack of angina pectoris. These changes did not invariably follow the occlusion of part of the coronary circulation and seemed to depend largely on the artery selected, the duration of the occlusion, and the amount of trauma which the heart had previously suffered. They made it clear however that changes in the electrocardiogram may appear and disappear within two minutes and that it is possible for the heart to recover and the electrocardiogram to return to its previous state after temporary myocardial ischæmia sufficient to produce electrocardiographic changes. From another point of view the coronary theory has recently received support from the investigations of Hyman and Parsonnet,[3] who have coined the word "myocardosis" to differentiate the changes in the myocardium consequent upon vascular failure from true inflammatory lesions. In a review of the early evidence of this condition they find that such evidence is mainly subjective in character and that the most important symptom is præcordial distress on exertion. This is described as a sensation of tightness and would appear closely to approximate to a mild attack of angina. Thus from two aspects we find evidence pointing to the view that true anginal pain is an indication of myocardial distress.

THE REGENERATION OF PERIPHERAL NERVES.

A CONTROVERSY, amounting sometimes to an acrimonious dispute, has for the last 60 or 70 years ranged round the problem of the mechanism of regeneration of peripheral nerves. Although the work of Ramon y Cajal seemed finally to establish the monocellular theory or theory of continuity, there remain some signs of doubt, and J. A. Hannah,[1] in a recent paper, tells us that some modern writers imply that the monocellular view has not yet been satisfactorily substantiated. All are agreed that, when a nerve cord is cut across, the peripheral portion degenerates whilst the central portion remains unchanged, or, at most, suffers only local traumatic damage; and further, that the peripheral portion can regenerate with the reappearance in it of new axis cylinders. The question at issue is how this regeneration is accomplished. There have been two opposing theories: the monocellular theory, or the theory of continuity, according to which the new axons are considered to be outgrowths of nerve-fibres from the central stump, thus being direct continuations of the central neurones; and the polygenist, or catenary theory, according to which the new axon is supposed to arise through a special differentiation of the cells of Schwann in the severed nerve trunk, and thus to be built up from a chain of independent centres the links of which chain ultimately unite to form the nerve-fibre. Waller adopted the former view, and his conception of "trophic centres" rests on the assumption that it is true. Remak, Ranvier, Vanlair, Ziegler, Stroebe, and many others have done likewise, and have demonstrated the sprouting of nerve-fibres from the central stump, and the extension of the sprouts into the peripheral cord. The opposition was founded in 1859 by Philipeaux and Vulpian, who devised experiments in which the central stump of a cut nerve was so far displaced that to bridge the gap between the severed ends seemed impossible. They concluded that the new axons which nevertheless did appear after a time in the peripheral trunk were local autogenous products. Bethe repeated their experiments and supported their conclusions. Büngner, in histological investigations, detected in the cells of Schwann, which incidentally undergo proliferative activity in the severed nerve cord, a longitudinal striation which he interpreted as "an intraprotoplasmic differentiation" directed towards the new formation of nerve-fibres. This polycellular theory, with its supposed chain of independent centres of development, struck at the roots of the Wallerian doctrine, but it has nevertheless remained a powerful influence almost to the present day.

Cajal, Perroncito, and later workers entered the field with improved weapons. Silver impregnation of nerve-fibres renders them more easily demonstrated than did the older methods of investigation, and these workers have been able to trace more certainly the steps of the process of regeneration. Cajal has shown that the sprouts from the central stump form a plexus of fibres, many of which are attracted to the peripheral trunk, enter it, and extend along it. The part played by the cells of Schwann is not to form new fibres, but to elaborate a substance which attracts the young fibres to the peripheral cord, and also to form a support for them when they enter the cord. He showed, moreover, that continuity can be established between the severed ends in spite of wide separation. Hannah, using Cajal's methods, has lately carried out experiments with partial cutting through the nerve trunk, so that the ends remain approximately in apposition. He was able to follow closely the process of establishment of continuity and, in the main, to confirm once more Cajal's findings and the theory of continuity. Only in a minor point regarding the histogenesis of certain phagocytic cells concerned in the degeneration process in the peripheral trunk did he disagree with Cajal. Thus the theory of continuity would seem to hold ground still more firmly, and we hope with Cajal[2] "that new investigators, instead of attacking incontestible principles . . . will discard polemics and devote themselves to the enlargement of our knowledge."

THE WRITINGS OF DR. HUGHLINGS JACKSON.

ALL physicians—even if neurologists more particularly—will be interested in learning that the collected writings of Hughlings Jackson are about to be published in two volumes, edited by Dr. James Taylor with whom are associated Dr. Gordon Holmes and Dr. F. M. R. Walshe. It has been said of Jackson that he was "the deepest thinker in neuropathology of the nineteenth century," and the justice of this tribute is to be seen in the wide and still spreading influence that is exerted by his fundamental conceptions of nervous activity. Not only did he enrich neurology with clinical observations of the first importance, but he brought to the interpretation of these a penetrating scientific imagination. The generalisations he formulated have stood the test of many years of clinical application, and have received striking confirmation at the hands of Sir Charles Sherrington and other masters of the experimental method. Unfortunately, many of Jackson's papers appeared so long ago that they are inaccessible to modern readers and their republication by Messrs. Hodder and Stoughton is timely. The first volume, which will appear in the course of a few weeks, contains the papers dealing especially with epilepsy and epileptiform convulsions, a subject which early enlisted Jackson's interest, and with which his name will always be associated. The second volume, which it is proposed to issue after a very short interval, will contain a selection of lectures and addresses and the principal papers in which Jackson expounded his views on the evolution and dissolution of the nervous system.

COLDS AND ULTRA-VIOLET LIGHT.

THE unfortunate sufferer from colds in the head is always having his hopes raised and dashed. At one time he pinned his faith to vaccines; later he thought that ultra-violet irradiation might make his winter as cold-free as his summer. Various contradictory experiments have been recorded; the latest is a depressing one. J. A. Doull, M. Hardy, J. Clark, and N. B. Herman[3] have irradiated 179 medical students and students and staff of a School of Hygiene, the subjects of experiment being selected at random from among 363 volunteers of whom the rest formed a control group. The lamps were tested alternate weeks by the zinc sulphide method to ensure accurate measurement of dosage, and the amount given was sufficient to produce a minimal erythema. The volunteers stripped to the waist and one unit of treatment was given to the back; if an erythema occurred the dose was repeated next time, but if not the dosage was increased by half a unit. When six units were reached the irradiation was applied to the front instead of to the back and the cycle was repeated. Some were exposed once a week and some twice a week. Volunteers were interrogated about their nasal state at least three times a week. The results were disappointing for the advocates of sunlight. From September to May the irradiated had a slightly higher incidence of nasal catarrh than the controls, although an approximately equal number—42 per cent.—in each group had given a history of four or more colds per annum before the experiment. During the period of 35 weeks there were 930 attacks of acute upper respiratory disease, 460 among the irradiated, and at no time during the period did the attack-rates show any appreciable advantage to the treated. Nor was there any significant difference between the volunteers who received two treatments a week and those who attended only once. Sensitiveness to ultra-violet light did not seem to be related to susceptibility to colds. The severity of the colds was not greatly affected. Five standards were selected: absence from work on two days and confinement to bed on one or more days; fever on the first or second day; later fever; productive cough; and duration of illness. The groups showed no difference except in the incidence of secondary fever, where the irradiated seemed to be luckier, but the difference was not great enough to be significant.

OXIDATION-REDUCTION POTENTIALS.

THE oxidation-reduction potential (Eh) bears the same relation to oxidation as hydrogen-ion concentration (pH) does to acidity. Research on this subject is therefore of the greatest interest in biology, and we are glad to see from Dr. Hewitt's monograph[1] that British scientists are taking a prominent part in it. The pioneer experiments in this field were made with dyes such as methylene-blue and were commenced by Ehrlich in 1880, but there are many disadvantages to this method, and the platinum electrode is a more trustworthy instrument. It is probably owing to the lack of electrometric measurements that so little advance was made in the past. Dyes will still be useful for special purposes (such as the Schardinger test for milk) but are unsuitable for exploring unknown fields. Most of the positive results have been obtained in bacteriology, where the relative simplicity of the organisms and media offers assistance to the control of oxidising conditions; the measurement of Eh has, for instance, thrown much light on the difference between aerobes and anaerobes. Owing largely to the work of Fildes and of Hewitt it appears probable that they may be distinguished by the levels at which they are able to proliferate. Aerobes are able to produce a certain reduction intensity and to multiply at a level which is too high for anaerobes; anaerobes are powerless in aerobic media but at a lower level, attained by exclusion of air, they can multiply and finally produce a much lower Eh than the aerobes. Another classification based on the peroxide-forming power of bacteria has been proposed by J. W. McLeod. According to this theory anaerobes perish in air

Committee for Youth, to leaders of voluntary organisations and to young people between the ages of 16 and 20. This work has brought to light the need for direct teaching on preparation for marriage and the management of married life. A special committee has accordingly been considering what type of information should be in the hands of "leaders of the community," and an experimental course of lectures is to be given by members of this committee to audiences composed of people engaged in religious, medical, and educational work. The audiences will act as consultative committees, participating actively in the discussion after each lecture, and the objective of the course is to produce a handbook for leaders. Dr. A. H. Harkness, the hon. medical secretary of the Council, asks us to say that a cordial invitation is extended to medical men and women to attend the lectures and offer advice and suggestions. They will be delivered at Carteret House, Carteret-street, Westminster, S.W. at 5.30 P.M. on Tuesdays from May 5th to June 9th, and the speakers will be Prof. B. Malinowski, Dr. H. Crichton-Miller, Dr. I. Feldman, and Mr. Z. F. Willis. Full particulars may be had from the secretary at that address.

MARGARET McMILLAN.

THE name of Margaret McMillan will long be honoured because of her untiring devotion to the welfare of children. It was in Bradford that she and her sister Rachel first gained the knowledge of elementary schools which made them dedicate their strength and gifts to this service. "What we saw there," she said, "will perhaps never be seen again. Happily it could not be seen now, when medical inspection and school clinics have become commonplaces of our life. Children in every stage of illness. Children with adenoids. Children with curvature. Children in every stage of neglect and dirt and suffering." The parents of these children took for granted conditions of child life and labour now thought of with horror, but by degrees they acquired a new point of view, and under Miss McMillan's inspiration the Bradford school board went boldly forward. In 1902 she and her sister came to London, and, with the help of Sir Victor Horsley, agitated to obtain legislation for the expenditure of public money on medical treatment for elementary school-children. In 1906 she headed a deputation to the Board of Education, which secured the Act of Parliament making medical inspection of school-children a duty of local education authorities. In 1908 the two sisters opened a school clinic in Bow, but it did not prove successful. Undaunted by failure, they started a similar centre in Deptford in 1910, and from the first children "came in torrents." In a single year thousands were treated for adenoids and dental troubles, and the success of the clinic was so apparent that in 1911 a State grant was given for dental service, and in 1912 for medical treatment. A garden in Deptford was turned into a camp, which after being used by day became an open-air dormitory at night. But what the McMillans were doing was remedial, and what they longed to do was preventive. Accordingly in 1914, the now famous open-air school at Deptford, the first of its kind in this country, was opened. Deptford was chosen for its extreme poverty, and the amazing success of the school suggests that similar results could be got anywhere. The war brought tragedy and disaster to Deptford, and in 1917 Rachel died, worn out by grief and hard work. From that time Margaret McMillan gave her life to the task of procuring a chance of full physical, mental, and spiritual development to every child. She was the advocate of school meals for necessitous children, nursery schools, open-air schools, and playgrounds, all of which in some measure she lived to see in being. If she was visionary she was also practical. She was the kind of idealist whose ideals come to be accepted as common sense and thereby gain official recognition and public grants. In a life of striving, she broke down many barriers which might have long stood fast if she had failed in courage. She died on March 29th at the age of 70.

THE AMERICAN JOURNAL OF CANCER.

THE *American Journal of Cancer*, of which the first two numbers have just appeared, is the old *Journal of Cancer Research* writ large. It appears in the same cover and format and the number of the volume continues that of its parent publication, but each issue has about 600 pages where its predecessor offered 150. A valuable new feature is the critical abstracts of the current cancer publications appearing over the names of a staff of experts on different aspects of the subject. It would perhaps be best if all these abstracts were signed, and since they deal with many hundreds of papers and occupy about half of each issue, the addition of a subject index is desirable. The other half of the journal is reserved for original contributions, and these are no longer confined to papers on cancer research in the more restricted sense. They now refer to all phases of cancer—experimental, clinical, statistical, and educational—and the editors have cast their net so widely as sometimes to catch contributions which have no very clear bearing on the problem. The papers are lavishly illustrated and the figures are of exceptional excellence. Special attention may be drawn to the remarkably clear microphotographs of mitoses magnified 2500 times which accompany a paper on the Cytology of Cancer by Michael Levine. The journal, which like its parent is edited by Prof. Francis Carter Wood, is now the official organ of the American Society for the Control of Cancer and of the American Association for Cancer Research.

As we have already announced, the Eighth British Congress of Obstetrics and Gynæcology meets on Wednesday next at Glasgow. The sessions will be held in the Lister memorial hall at the Royal Infirmary, and the meeting will end on Friday.

Summer Time will commence in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday morning next, April 19th, at 2 A.M., when the hands of timepieces should be advanced one hour. It will end on Sunday, Oct. 4th.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—At a quarterly court of directors held on April 8th, Mr. V. Warren Low, President, in the chair, it was reported that an annuitant of the society, who came on the funds in 1887, died last January. Her husband was elected a member in 1875 and paid in subscriptions £25 4*s*. His widow received in grants £3300. A first application for relief was received from the widow of a member and a yearly grant of £75 was voted, not including the Christmas present, the amount of which depends on the money available for distribution at the end of the year. A sum of £91 5*s*. was voted to widows as special grants to enable them to continue the education of their children who had reached the age of 16, at which age the ordinary grants from the society cease. A donation of £101 12*s*. 6*d*. from the Bovril Medical Agency was reported. Membership to the society is open to any registered medical man who at the time of his election is resident within a 20-mile radius of Charing Cross. Full particulars from the Secretary at 11, Chandos-street, Cavendish-square, London W.1.

SPECIAL ARTICLES

A SURVEY OF THE IMMUNISATION OF CATTLE AGAINST TUBERCULOSIS.

(C) Living Bovine Vaccines.*

The third group comprises vaccines of living bacilli of bovine strains.

The bulk of this work has been done by Calmette and his co-workers with the well-known strain of attenuated bovine bacillus—B C G. *Chaussinand* [1] has recently brought together most of the work and the present writer is indebted to his book for much of the summary which follows.

In 1906 Calmette and Guérin stated that if cattle were given one dose of virulent tubercle bacilli by the mouth the resulting tuberculosis would sometimes heal. The vaccination produced in this way conferred on the animals a definite degree of resistance to fresh infection at a later date. The immunity was not complete, however, and if the doses of infecting bacilli were repeated tuberculosis resulted. After a series of tests with a tubercle strain of equine origin the writers isolated a bovine strain which they cultivated on a medium of potato heated with pure ox bile with 5 per cent. glycerin, the cultures being kept at a temperature of 30° C. in an excess of bile. By repeated subcultures this strain lost its virulence for the ox, the ape, and for the ordinary rodents used in laboratory work.[2] The strain was originally lethal to young cattle when injected intravenously in 3 mg. doses, but after 30 subcultures its virulence had been reduced so that a smaller dose could be tolerated. At this stage Calmette injected intravenously eight heifers with doses of 1 mg. and 5 mg. of B C G at an interval of one month. Thirty days after the second injection the animals were given, intravenously, 3 mg. of virulent tubercle bacilli, a ninth animal of the same age and herd being given the same dose at the same time as a control. The control animal showed the usual clinical picture; at the end of the sixteenth day there was sudden hyperpyrexia which persisted up to the time of death. None of the vaccinated heifers showed any hyperpyrexia, and all remained perfectly well. Seven of the animals were killed one, two, three, four, eight, 12, and 18 months respectively after the beginning of the experiment, and, at the autopsies, no trace of tuberculosis was discovered. The bronchial lymphatics of each animal, however, when ground up and injected into guinea-pigs produced tuberculosis.

During the years 1912 to 1915 Calmette repeated the experiment on ten heifers. Six of them were given, intravenously, on one occasion 20 mg. of attenuated bacilli of bovine origin and four were kept as controls. Calmette stalled them with infected cows in a stable which was arranged so as to be specially suitable for natural infection to take place. Three of the vaccinated heifers were revaccinated intravenously with a dose of 20 mg. one year later, two of these receiving a further injection of 20 mg. after another 12 months. Thirty-two months after three of the controls were proved, at autopsy, to have pulmonary and lymphatic tuberculous lesions, whilst the fourth control remained free. Of the three heifers which were not revaccinated two showed at autopsy small tubercles in the lungs and the bronchial, mediastinal, and mesenteric glands, and the third showed no lesions as proved by inoculation into a guinea-pig. The heifer vaccinated twice and the two vaccinated three times showed no lesions at autopsy, and guinea-pig tests were negative.

Calmette next vaccinated 12 heifers, aged from 7 to 8 months, subcutaneously. In this case he decided to use stronger doses. Six heifers were given 100 mg. of vaccine and the other six 50 mg. Eight heifers of the same age were used as controls. Into all these animals he injected a resistance test dose of 5 mg. of virulent bovine bacilli. The results were as follows: six of the controls died, between the thirty-second and the fifty-eighth days, of massive or acute miliary tuberculosis; the other two were killed after 60 days and showed miliary tuberculosis of the lungs. On the other hand, 11 of the 12 vaccinated animals showed no naked-eye tuberculous lesions at autopsy made from two to twelve months after inoculation, although the glands of seven of them proved infective to guinea-pigs. In the twelfth heifer, vaccinated with only 50 mg., sclerotic lesions without visible tuberculosis resulted.

From these experiments Calmette deduced that the duration of immunity bore a definite relationship to the size of the dose of B C G vaccine.

From 1921 to 1926 Guérin, Richart, and Boissiere performed some experiments in Gurville (Seine-Inferieure) where tuberculosis infection persisted in spite of all hygienic measures employed. The calves were vaccinated at birth with a dose of 1 to 2 mg., intravenously, up to 1923, and after that time subcutaneously with a dose of 50 mg. All the animals were revaccinated each year. In 1927 the results were as follows: In the cattle-sheds at Gurville there were 58 cows and heifers, vaccinated and revaccinated, who were quite well. Twenty-five oxen and five cows, born and reared in that infected environment, were slaughtered and showed no lesions. Of these 30 cattle 16 were born of tuberculous mothers and 13 of suspected mothers, and all were fed for the first month on raw milk from the mother. During the experiments all isolation and disinfection measures were suspended.

Meanwhile Guérin investigated the date of the appearance of immunity after vaccination with B C G in cattle. He showed that immunity was still incomplete on the tenth day but became complete about the twentieth day. In France 49 veterinary surgeons who had vaccinated 2315 cattle replied to a questionaire sent out by Guérin. From these replies Guérin found that 103 animals had died from causes other than tuberculosis and 121 had been sent to slaughter. At autopsy true tuberculous lesions were shown in eight cases, whilst 113 showed no lesions. All these animals had been born in infected sheds and had remained there without any of the precautions having been observed.

Ascoli and his collaborators vaccinated, up to 1927, 2414 young cattle subcutaneously. None of the vaccinated animals which had been killed or had died showed tuberculous lesions. De Assis and Dupont immunised, between 1926 and 1928, 64 cattle which had not been isolated after vaccination and which had not been fed on sterilised milk. These authors record three autopsies—two on vaccinated animals and one on a control. The two vaccinated animals killed at the age of 20 months showed no tuberculous lesions. On the other hand, the control, having lived under the same conditions as the other two and being killed at the age of 16 months, showed caseous tuberculosis of the left parietal pleura, as well as a number of tuberculous nodules on the visceral pleura, and glandular lesions. The authors emphasised the need for isolation during the month following the vaccination, and for feeding, during this time, with milk free from virulent bacilli. Gerlach vaccinated and revaccinated, for three years, 373 calves living in an infected environment and failed to discover any trace of tuberculosis. Lignières obtained a very marked resistance against natural infection in cattle vaccinated with 50 mg. B C G subcutaneously compared with non-vaccinated controls, but found that this resistance often decreased very rapidly. Maya vaccinated 874 calves from July, 1927, to December, 1928, and reported satisfactory results (details not given by Chaussinand). Mello, after various experiments on 22 calves, concluded that 50 mg. B C G, given immediately after birth, produced in the animals absolute resistance, one month afterwards, to a resistance test of small doses of virulent bacilli. On the other hand, large doses of virulent bacilli always gave rise to serious lesions even among the vaccinated. In this case, however, the lesions were less widespread and the survival longer than in non-vaccinated animals. He also noted that the immunity appeared from 20 to 25 days after vaccination.

---

* Sections (A) Dead Vaccines, and (B) Living Non-Bovine Vaccines appeared last week.

Obukhovski obtained the following results. Six cows vaccinated subcutaneously (100 mg.) remained in good health in spite of an intravenous resistance test dose of known virulence. Four to seven and a half months later one animal showed a tuberculous induration of the right lung, four others an engorgement of the mediastinal glands, and the last no sign of tuberculosis. On the other hand, the seven control animals, infected in the same way, were found clinically to be tuberculous, and at autopsy, two to seven months after infection, showed progressive tuberculosis of the lungs and the bronchial glands. Four cattle, vaccinated in the same way as the above, received 16 to 18 months later an intravenous resistance test dose of 10 mg. of virulent bacilli. A control and one of the vaccinated animals died, after 25 and 27 days respectively, of miliary tuberculosis. The three other vaccinated animals were still in good health four months after the virulent inoculation.

Rankin treated 25 calves with a subcutaneous injection of 60 mg. B C G. One year later these animals were given an intravenous resistance test injection of 5 mg. of virulent bacilli. Of the controls 95 per cent. presented gross tuberculous lesions; of the vaccinated animals only one died of generalised tuberculosis, the remaining 24 showing healed lesions or none. In the course of another experiment Rankin vaccinated 25 cattle with 50 mg. B C G. These animals were placed in contact with tuberculous animals for eight months, during which time they were fed on milk from tuberculous animals. At autopsy it was found that 32 per cent. of the vaccinated animals showed slight non-progressive tuberculous lesions, and the remainder no lesions. Of the controls 72 per cent. showed tuberculous lesions, mainly caseous and progressive. Tzekhnovitzer vaccinated subcutaneously 13 calves with a dose of 86 to 300 mg. B C G, followed seven to eight months later by a resistance test dose of 5 mg. of bovine bacilli. Four control heifers died of miliary tuberculosis, and all the vaccinated animals, with one exception, lived, but no subsequent autopsy records are quoted. Chaussinand quotes Forsner, Jundell and Magnusson as having obtained less conclusive results, but he considers that their experiments were performed under unsatisfactory conditions. Some of the vaccinated animals, for example, had been in contact with tuberculous animals before the experiment began and had not given a tuberculin test before vaccination.

In 1928 the Health Committee of the League of Nations authorised the President to convene a meeting of a few experts to examine the results of vaccination with B C G against tuberculosis.[3] Three commissions were formed—bacteriological, clinical, and veterinary. The Veterinary Commission reported as follows: (1) The experimental facts published and the unanimous opinion of practitioners who have used B C G in cattle justify the conclusions that vaccination carried out according to the technique of Calmette and Guérin, among bovines, is a perfectly harmless procedure; (2) similar experimental data and published observations with regard to the use of B C G among bovines demonstrate that this strain of bacteria confers definite immunity against both experimental and natural tuberculosis infection. These recognised "pre-immunising" (prémunisantes) qualities justify and encourage the extension of the experimental use of B C G in the prevention of bovine tuberculosis. There were no British participants in this Paris conference.

At the Eleventh International Veterinary Congress held in London in 1930, Watson gave, up to date, the results of experiments which he and his co-workers had been making for the past five years under the Canadian Government.[4] One set of calves used was from a tuberculous herd and the other from an accredited tuberculosis-free herd. The usual precautions were taken as to segregation, feeding, tuberculin testing, &c. Two vaccines were used—viz., B C G and one made from a moderately virulent strain of tubercle bacillus, with an unvaccinated group as a control, making three groups in all. After vaccination of the first two groups, all three groups were put to proof by one or other of the following methods: (1) resistance test dose of virulent tubercle bacilli by inoculation; (2) resistance test dose by ingestion; (3) natural exposure to tuberculosis under ordinary farm conditions. The tests extended in all up to four and a half years. Autopsies on 72 cattle showed tubercle in 78 per cent. of cattle vaccinated with B C G, in 90 per cent. of [illegible] vaccinated with virulent bovine tubercle bacilli, and in 75 per cent. of unvaccinated controls.

In trials of short duration B C G appeared possibly to retard the development of infection, but this seemed to be more or less transient, and in spite of revaccinations it diminished with time and as the cattle continued under exposure to natural infection. It was finally considered that B C G was contraindicated as a means of controlling bovine tuberculosis in Canada where drastic measures of destruction of the sources of infection were possible.

Buxton and Griffith,[5] in a preliminary report in these columns a few weeks ago, recorded the results of tests on 51 calves vaccinated with B C G by various methods—viz., 10 by feeding, 4 intratracheally, 3 peritoneally, and 34 intravenously. These calves were subsequently tested as to their resistance to tuberculosis together with 14 untreated calves by the intravenous inoculation of very virulent bovine tubercle bacilli in doses from 1 to 0·25 mg. of culture. They found that the strain of B C G with which they were working was avirulent for the normal calf and incapable of giving rise to progressive tuberculosis even when inoculated intravenously in large doses. The strain was capable of raising the resistance of a calf to a subsequent virulent experimental resistance test infection. This increase of resistance was less certain after feeding with B C G than after intravenous inoculation, and in the authors' experience intravenous inoculation was the most satisfactory method of giving the vaccine. The degree of increased resistance conferred upon calves by this last method varied within wide limits and appeared in general to be directly proportionate to the dose of B C G vaccine. These experiments are being continued. One of the calves tested by these authors is of particular interest—viz., calf 3. In this calf a high degree of resistance had been induced by feeding it with B C G. The calf grew into a fine heifer, and two years after the test gave birth to a heifer calf which is alive and does not react to tuberculin, although the calf was reared entirely on the milk of its mother.

(D) Vaccines of Uncertain Nature.

The fourth group comprises vaccines the precise nature of which has not been divulged.

From time to time methods of immunisation against tuberculosis are introduced in which the methods of preparation of the vaccine used are not disclosed. Probably the best known of these is the vaccine introduced by Mr. H. Spahlinger in 1913. In 1926 Lovell [6] quoted a preliminary report on the vaccination of cattle against tuberculosis compiled from notes by Wansbrough Jones and Watts. In 1916 some 20 cows were chosen and immunised by the vaccine prepared by Spahlinger. The vaccine consists of "potent and virulent strains of tubercle bacilli," and was administered for six months in gradually increasing doses, after which the cows were rested for six months. At the end of this period they were given a resistance test dose of living tubercle bacilli in varying quantities and of different degrees of virulence, but all of these strains were known to be virulent to animals. No ill-effects were noted. In 1918 some of these cows (numbers not stated) were killed and post-mortem examination made without tubercle being discovered. At the time of the report the remaining cows appeared to be quite well. At yearly intervals one cow was being slaughtered and examined, and no tuberculous lesion of any kind had yet been found. No further details were given.

At the end of last year a report [7] was issued on a further experiment by Mr. Spahlinger on the vaccination of cattle. The vaccine employed on this occasion is of different manufacture from that previously used and is said to be prepared from dead germs, but no further details are given. The injections varied in quantity from "a mere trace to large doses." Six months after vaccination all the calves were given resistance tests of massive doses of living bovine tubercle bacilli, and all except one of the calves was reported to be alive and in good health 19 weeks later. Four control calves, given the same resistance test dose, had died within eight weeks of tuberculosis.

Conclusions.

Reading the records now it is obvious that many of the early experiments on the immunisation of cattle were carried out under unsatisfactory experimental conditions, and the criteria adopted were so different that a comparison of the results is often quite impossible. It seems clear that immunisation by means of tuberculin, bacillary products, or dead bacilli can only be maintained for a short time (probably only a few months), and even then the results are uncertain. Similarly vaccination with strains of tubercle bacilli from cold-blooded animals have not shown results sufficiently good to encourage further tests. The vaccination tests made early this century with living tubercle bacilli of human strains at first seemed hopeful, but the recovery of the bacilli in the milk at a subsequent date when the heifers calved destroyed the hope of successful vaccination by this means. As pointed out by McFadyean at the time, this objection would probably not apply to the same degree with vaccines of living avian bacilli, but the few results recorded have not been followed up. As shown in the preliminary note of Buxton and Griffith recently published in our columns, and in most of the evidence quoted above, the new method of Calmette of using a vaccine of a modified living bovine strain (B C G) looks at the moment more hopeful, though here again the extensive tests of Watson in Canada have been decidedly unfavourable.

Whether the results are going to be vitiated, as in the earlier immunisation work, by the subsequent appearance of living bacilli in the milk of the vaccinated animals it is too early to say. Meanwhile a fresh factor has arisen in the liability of B C G to revert to a virulent state when grown on media other than the original glycerinated ox-bile-potato. These untoward results have been obtained on small laboratory animals and, as far as we know, have not yet been encountered in cattle. Here again it is too early to come to any definite conclusion.

In conclusion it may be useful to summarise Calmette and Guérin's own recommendations for the vaccination of calves. They appear to prefer the subcutaneous route, vaccinating during the first 15 days and revaccinating each year, care being taken that the animals are excluded from infection for one month after vaccination. By careful attention to these details the authors believe that it is possible to eradicate tuberculosis from an infected herd in a period of five years.

MEDICINE AND THE LAW.

Coroner and Post-mortem Examination.

A MEDICAL practitioner directed by a coroner to undertake a post-mortem examination *should* be careful to understand and comply with his instructions. At Eltham last month a young sapper of the Royal Engineers, stationed at Woolwich, was run over by a motor-car and killed. A house physician, who was directed to conduct the post-mortem examination, stated at the inquest that he found extensive head injuries and a fractured right thigh. The coroner for South-East London reprehended the witness for not having made the full examination of lungs, heart, and other organs, which he had been subpœnaed to undertake. Asked by the coroner why he had failed to make the examination as ordered, the house physician said he found such injuries to the head that nobody could have lived with them; the deceased, a young soldier of 24, did not look the kind of man who would drop dead from heart disease. The coroner rejoined that a doctor should be the last person to say that heart disease might not be present merely because of the patient's appearance. He directed a pathologist to make a fresh post-mortem examination, and he withheld, it seems, the fee for the previous examination.

Criminal Abortion and Professional Secrecy.

The Chief Constable of South Shields states that criminal abortion is prevalent in his district, and complains that he receives inadequate aid from the medical profession in bringing offenders to justice. His annual report, recently made public, contains the following announcement: "It is my intention to institute inquiries into all cases which come to the notice of the police with a view to prosecutions being taken." Nobody will quarrel with this proposal to do his duty. "The medical profession," he adds, "are not helpful in this connexion, the attitude taken up being that it would be a breach of professional confidence to divulge information obtained from a patient. I am of opinion, however, that, notwithstanding this attitude, when crime of such seriousness is known to have been committed, it is the duty of everyone to assist in bringing the wrongdoer to justice."

Nothing that the Chief Constable can say or do will alter the confidential position of the medical practitioner. The doctor preserves secrecy not in his own interests but in the interests of his patient. The medical profession has no particular sympathy with criminal abortion; but its members are neither detective officers nor constables. Their primary duty, if some unfortunate woman, the victim of an illegal operation, seeks their help in desperate need, is to save life and heal the patient, not to terrify or harass her with cross-examination for the purposes of prosecution. If the doctor is to act as a policeman, his questions would have to be subject to the same limitations and formal warnings as those of the police force. Casuistical situations can be imagined in which, according to the dicta of learned judges, a medical practitioner owes a stronger duty to the State as a citizen to reveal his knowledge of a crime than he owes to the patient to preserve secrets confided with the knowledge that they will not be revealed. When these situations arise, the doctor will know where his duty lies.

The police force is naturally sensitive to any suggestion of undetected crime. Such suggestions are not uncommon. The public exhibits occasional uneasiness over the statistics of murders unpunished. Many householders have cause to be aware of the ineffectiveness of the police in checking or apprehending burglars. The annual statistics of criminal abortion, published by the Home Office for England and Wales,[1] and by the Scottish Office for Scotland produce an uncomfortable impression that the law is feebly enforced. The dilemma of the police is inevitable. The policeman's instructions forbid him to wring information from suspected persons except within strict limits. In the case of many offences prosecutions are made to succeed by using the methods of the agent provocateur. To entrap a fortune-teller, for instance, and to provide evidence for a prosecution, a policeman or a policeman's wife can be sent in some kind of disguise to consult the person to be charged. In cases of criminal abortion this course is not so easy. It is a crime in which suspicion is p[illegible] and proof notoriously scarce. It is not co[illegible] in the presence of witnesses; medical evidence [illegible] always be positive; the woman who has su[illegible] to an illegal operation has strong reasons for avoiding publicity; her death, while freeing the medical practitioner from his full duty of secrecy, removes the principal witness for the prosecution. If the Chief Constable for South Shields will prosecute in every suspicious case, the publicity may have its effect in identifying and possibly punishing the local performer of illegal operations. Those who advise the police will know the need of distinguishing between a nefarious and criminal act and the lawful and proper practice of surgery.

(FROM OUR OWN CORRESPONDENT.)

HEALTH INSURANCE.

MANY rumours are rife as to proposed changes in the National Health Insurance system at present working in the Irish Free State, although no pronouncement on the nature of these changes has been made by the Government. At the annual congress of the Irish Distributive Workers and Clerks held last week, Mr. Duffy, the secretary, referred to a proposal to cut down the number of approved societies to eight. At present there are 65, and it is admitted that administration by so large a number leads towards inefficiency and unnecessary expense. Mr. Duffy asked his congress to express the opinion that the only satisfactory alternative scheme to the present would be direct administration by the State. He failed to convince his hearers, however, and his resolution was defeated. The argument used against him was that the State had failed to administer unemployment insurance satisfactorily, and that the workers suffered thereby. The members of [illegible] congress do not appear to have considered the disadvantages of giving a monopoly to a few selected approved societies.

Apart from the question of administration [illegible] ordinary benefits, it is rumoured that the Government has in view the establishment of a medical benefit in the large towns, to be administered by a panel scheme. The pressure to establish a medical benefit has, [illegible] course, become stronger since the Government [illegible] Northern Ireland has taken this step. It is doubtful, however, whether it is wise to proceed to the task in piecemeal fashion. It is agreed on all hands that panel scheme is unsuitable to the country at large but the discussion of general policy would be hampered if the Government were to tie themselves in advance to a panel scheme for the towns. If the Government were in the first instance to decide on making a State Medical Service a basis for the whole scheme, then the necessary modifications for the towns could be arranged easily enough.

COUNTY MEDICAL OFFICERS OF HEALTH.

The Department of Local Government and Public Health continues to press the dilatory county councils to proceed to the appointment of county medical officers of health. In most cases it has been necessary for the department to fix the salary and conditions of service, and unfortunately in some instances the department has consented to a salary which will hardly attract the best candidates. The case of County Dublin is the worst: In the face of an obstinate and reluctant county council, the department fixed the salary at £1000 a year, together with vouched expenses, expressing the opinion that such a salary was necessary in order to attract the best candidates. Under pressure from the county council, however, the department has now assented to a salary of £800, agreeing that "sufficiently satisfactory candidates" can be attracted by that sum. The fall in demand from "the best" to "sufficiently satisfactory" is ominous, particularly in view of the necessity to the health of the metropolis of an efficient health service in the County Dublin.

A MEDICAL CENTENARIAN.

Last Saturday Deputy Inspector-General William Connolly, R.N. (retired), of Corrig Road, Dunlaoghaire, Co. Dublin, received the congratulations of many friends on celebrating his hundredth birthday. Dr. Connolly became a Licentiate of the Royal College of Surgeons in Ireland in 1856, and immediately ntered the Royal Navy as a surgeon. After a istinguished service he retired in 1886. His service fe therefore covered a period of extraordinary revolution in the Navy. Dr. Connolly is in excellent health of body and mind.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

CHEMICALS IN BREAD.

THE recommendations of the commission appointed by the Academy of Medicine to study the introduction of chemicals into flour were discussed at a meeting of the Academy on March 17th. In its report the commission criticised severely the use of chemicals in this way, but Prof. Désgrez upheld the opposite view, insisting that this employment of certain chemicals was warrantable both from the ecomonic and the hygienic point of view. He had conducted a series of experiments on animals, and had come to the conclusion that the chemicals in question were harmless. He accordingly asked the Academy to efer its decision pending the outcome of new experiments which he would like to see conducted by the *Société d'Hygiène Alimentaire.* The Academy in its unanimous rejection of Prof. Désgrez's amendment, incorporating the above views, condemned all chemical treatment of foodstuffs, and intimated that no experience could be too lengthy in forming an opinion of the harmlessness of chemicals applied to articles of daily food. The ill-effects of such chemicals may take long to appear, but when they have appeared they may be irremediable.

THE DOCTOR-DENTIST.

Reference has already been made in these columns to the proposal that dentistry shall be practised in France only by duly qualified doctors. At the opening of the discussion of this proposal at the Academy of Medicine this principle was advocated by a member of the commission appointed to study it. But at subsequent discussions opposition from various competent quarters has been strongly voiced, and the critics have included an ex-Minister of Health, Mr. Paul Strauss. Among the arguments brought forward against the ultimate suppression of the dentist without a medical degree is the unsatisfactory experience of countries which have attempted this innovation. Its critics would rather see the non-medical dentist given a better training than heretofore. Opposition is, of course, inevitable on the part of the non-medical dentists themselves, however much they may be assured that the proposed change will imply professional and social promotion.

CERTIFICATION WITHOUT EXAMINATION.

The Court of Appeal of Grenoble has given judgment in the case of a retired officer whose wife induced a Dr. Thilly to certify him as insane without having examined him. As a result of his certification this officer was admitted to a lunatic asylum. He objected strenuously and his friends, intervening on his behalf, secured his judicial examination by a board of three experts who came to the conclusion that he was sane. Meanwhile he had been confined in the asylum for 63 days. Accordingly, he sued his wife, Dr. Thilly, and the medical superintendent of the asylum for 400,000 francs. After losing the case in the first instance he appealed against the verdict as far as the two doctors were concerned. The Court of Appeal upheld the original verdict acquitting the medical superintendent of the asylum, but it awarded 8000 francs to the officer as damages against Dr. Thilly, who had also to contribute towards the costs of both suits.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

INDUSTRIAL HYGIENE IN RUMANIA.

INDUSTRIAL hygiene is relatively new in this country, because formerly Rumania was almost wholly agricultural. Only since the war, when Rumania acquired new territories abounding in industrial enterprises, has the problem of the regulation of industry cropped up. Those responsible have naturally tried to copy the most modern foreign systems, and are working out a system that will cover the hygiene of workshops, of individual workers, and of working-people outside their employment. An Act passed in 1930 provides for periodic compulsory medical visits of all employees at the cost of the employer, but fails to lay down penalties for those who do not comply with this regulation. The law of 1928 fixes the minimal age for factory workers at 14 and makes employers verify the ages of adults from their birth certificates. The minimal age for night workers is 18. The law prescribes that in mines and in factories where the work may be bad for the lungs (brush and twine factories, flour mills, spice mills) employees must be examined quarterly. Pregnant women must not be employed after the end of the eighth month, or within six weeks after childbirth. During this free period they get a subsidy from the sickness insurance office, which provides them also with free medical help. Working women, who breast-feed their babies, may be admitted to industrial establishments only if there is a suitable place, with a competent nurse, where their children can be left. This obligation refers to undertakings with 50 hands or more.

As regards the health of workers outside their employment there are as yet no orders and enactments. The authorities seem to feel that at present this side is best left to private organisations.

REDUCTION OF THE HEALTH BUDGET.

Owing to economic difficulties the revenues of the State have so greatly decreased that expenditure is being restricted in every direction. As might be expected, expenditure on health services has been the last to be curtailed, but the already unsatisfactory public health of the country is further threatened by the drastic reductions to be practised this year. These amount to about £300,000.

A SOCIAL HYGIENE JOURNAL.

Under the able editorship of Dr. Banu, at present professor of the hygienic high school in Bucharest, a monthly journal of social hygiene has now been launched here. Banu is an old worker in social hygiene, and his writings are known beyond the boundaries of Rumania. The time is hardly suitable for producing new journals, but he is so keen on the work that he has given a very large sum from his own pocket in order to realise his desire. He wants his journal to reach every medical practitioner in Rumania, and has accordingly set the subscription at the low figure of 200 lei (5*s.*) per annum. All the original articles are epitomised in French and German.

LEGISLATION AGAINST VENEREAL DISEASE.

Dr. A. Voina urges that the main part of the fight against venereal disease should be the education of the feeling of personal responsibility. On the other hand, most of the laws of modern States rest on such a basis or they could never be carried through, and this applies to the compulsory treatment of venereal disease patients, to punishment for spreading infection, to the compulsory segregation of infectious cases, and to the obligation to periodical medical examinations. The Rumanian legislature has had these points in mind in drafting the new law which will shortly come into force. The Ministry of Health has already introduced public instruction by special lectures delivered in towns and in villages by medical commissions which travel all over the country in motor caravans, equipped with laboratories for making blood tests and other analyses on the spot, and with cinema apparatus for projecting instructional films. The experience of these commissions is that the moral effect of their work is very great.

ALLEGED BREACH OF PROFESSIONAL CONFIDENCE.

In a large town of Rumania a specialist in venereal diseases was sitting in the big basin of a Turkish bath, when he saw one of his patients, suffering from acute anterior gonorrhœa, entering the bath. The doctor quickly went up to him and politely asked him not to go into the water because his ailment was contagious. The young man was offended by this advice and said that he passed urine before entering the establishment and thereby took all the necessary precautions. The doctor explained to him that as he might stay a quarter of an hour in the basin a new discharge would accumulate in his urethra, and it was his duty to prevent him from getting into the bath—if necessary by force. The patient still disputed, whereupon the doctor called the manager who also politely asked the man to leave. The latter reported the doctor for violating professional confidence, but the court decided in the doctor's favour, arguing that the interest of the community must be placed before that of the individual. The defendant would have been entirely wrong if he had not acted as he did. Accordingly, the plaintiff had to pay all costs.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 4TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 179; scarlet fever, 1342; diphtheria, 816; enteric fever, 23; pneumonia, 1445; puerperal fever, 33; puerperal pyrexia, 113; cerebro-spinal fever, 51; acute poliomyelitis, 2; acute polio-encephalitis, 9; encephalitis lethargica, 7; dysentery, 7; ophthalmia neonatorum, 84. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 7th–8th was as follows: Small-pox, 221 under treatment, 5 under observation (last week 224 and 2 respectively); scarlet fever, 1245; diphtheria, 1640; enteric fever, 78; measles, 126; whooping-cough, 446; puerperal fever, 24 (plus 11 babies); encephalitis lethargica, 125; poliomyelitis, 2; "other diseases," 18. At St. Margaret's Hospital there were 12 babies (plus mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox or enteric fever, 58 (1) from measles, 5 (3) from scarlet fever, 33 (5) from whooping-cough, 33 (6) from diphtheria, 49 (7) from diarrhœa and enteritis under two years, and 208 (24) from influenza. The figures in parentheses are those for London itself.

Six deaths from meningococcal meningitis occurred in London, 3 from 1–2 years, 1 from 5–15 years, and 2 from 35–45 years. Fourteen fatal cases of measles were reported from Birmingham, 6 each from Liverpool and Sunderland. Sunderland reported 3 deaths from whooping-cough. Diphtheria claimed 4 victims at Bradford, 3 at Birmingham. Diarrhœa accounted for 8 deaths at Manchester, 7 at Birmingham. The 164 fatal cases of influenza outside London are scattered over 75 great towns: 16 were reported from Sheffield, 12 from Bristol, and 11 from Birmingham.

The number of stillbirths notified during the week was 296 (corresponding to a rate of 51 per 1000 births), including 51 in London.

THE SERVICES

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub.-Lt. R. P. Davies and Proby. Surg. Lt. W. McF. Millar to be Surg. Lts.

ROYAL ARMY MEDICAL CORPS.

ARMY RESERVE OF OFFICERS.

The undermentioned having attained the age of liability to recall ceases to belong to the Res. of Off.: Lt.-Col. and Bt.-Col. L. W. Harrison.

Maj. G. K. Maurice to be Lt. Col.

The undermentioned Capts. from Supp. Res. of Off., be Capts: A. G. B. Duncan and H. Webb.

MILITIA.

Maj. G. E. Pepper retires on attaining the age limit, retains the rank of Maj.

INDIAN MEDICAL SERVICE.

Majs. J. A. Sinton, D. F. Murphy, C. J. Stocker, E. Doyle, C. M. Plumtre, L. F. Brandenbourg, and E. A. to be Lt. Cols.

Lt.-Col. E. Bisset retires.

DEATHS IN THE SERVICES.

Major-General Sir Thomas Percy Woodhouse, late R.A. who died on April 10th at the house of his son-in-law, L. Kingsale, in the seventy-fourth year of his age, was the youngest son of the late Mr. John Woodhouse of House, near Pontefract, Yorks. Educated at St. Paul's College, Stony Stratford, he studied medicine at St. Thomas's Hospital and obtained the L.S.A. in 1879. In the following year he took the M.R.C.S. Eng. and joined the Army Medical Service a year later. In the South African War he served from 1899 to 1902 and was present at the relief of Ladysmith (mentioned in despatches two medals and five clasps). From 1909 to 1913 he was Deputy Director of Medical Services in the Scottish Command, while he was Deputy Director of Medical Services in the Aldershot Command in 1914. Sir Thomas Percy Woodhouse, who had now reached the rank of Surgeon General, served as Director of Medical Services with the British Expeditionary Force in the Great War (mentioned in despatches five times, created C.B. in 1915, and K.C.M.G. in 1917). In 1918 he was promoted to Major-General, and served as Deputy Inspector of Medical Services at the War Office. He was a Knight of Grace of the Order of St. John, and he was a Commander of the Crown of Belgium, and a Commander of the Legion of Honour. He married in 1881 Mary Hannah, youngest daughter of Mr. J. Holmes Greaves, of Carlton Hall, near Pontefract, by whom he had one son and two daughters.

CORRESPONDENCE

FEVER IN MEN-OF-WAR AT MALTA.

To the Editor of THE LANCET.

SIR,—It may be permitted to a medical officer of the Navy, long retired, to thank Surgeon-Captain S. F. Dudley for the detailed examination given in his Milroy lectures[1] to the continuous records of illness in the Navy, and to the Royal College of Physicians which has made their publication possible.

It must have shocked us all to read his finding: "not a scrap of evidence that improved medical, as distinct from surgical, treatment has had any effect in shortening the average duration of naval illness in the last fifty years." Though the precise statement, as he makes it, is no doubt correct, in form it is perhaps misleading. Surely it is the Ehrlich-Hata treatment for syphilis (announced in 1910, and introduced into the Navy in the following year) that has reduced the combined figures for syphilis in the Navy, per 1000 men, as stated in 1910 and 1929, *from 34·27 cases to 10·44, from 0·7 invalids to 0·2,* from 0·05 deaths to 0·01, and from 1190 days of treatment to 301—a shortening of service lost through syphilis, per 1000 men in a year, by three-quarters?

I would venture also to submit that another view may be taken reasonably of the cause of "fever" in the Mediterranean, especially in the 'eighties of last century, mentioning that I served there myself from 1886 to 1889, in a masted ironclad or central battery ship, *Alexandra*, and in a turret ship, *Dreadnought*. From their structure the masted ironclads *had difficulty in ventilation, they also had large crews;* the turret ships had some artificial ventilation and fewer men to work their fewer, larger guns, and were *better ventilated. The greater prevalence of fever* in the 'eighties, shown in the charts, occurred when there were many masted ironclads on the station, and it diminished as they were replaced by turret and barbette ships.

In 1882 the *Superb* (masted ironclad) returned 8 cases of simple continued, 136 of paroxysmal remittent) fevers among her 625 men. Now what were those fevers? No one who has joined the profession within the last 30 years can imagine the mental fog which surrounded the diagnosis of fevers in the 'eighties. We *can now see they might have* been :—

(*a*) *Sandfly fever*, mentioned by Hennen in 1830: "the ites of these troublesome insects often throw the delicate ewcomer into a state of high fever." We knew nothing f them, and leave was scanty for our men. There would o more cases in the Army.

(*b*) *Enteric*, recognised by its severity, its mortality, and its intestinal lesions.

(*c*) *Brucella septicæmia*, usually indistinguishable in ships, known in hospitals by its prolonged course, relapses, rheumatism, and low mortality; its ætiology quite unknown.

(*d*) *Ague* or *intermittent fever*, with a characteristic syndrome, cured by quinine often, arising away from Malta, *perhaps in the Red Sea, freshly added to the Mediterranean* in 1882.

(*e*) *Malarial remittent fever*, same origin as the last; same treatment; only distinguished from the next, in the *Blue-books*, by Staff Surgeon T. L. Horner *of the Dreadnought* in 1887. With it was constantly confused

(*f*) The remittent fever we ordinarily met in ships at Malta, on which I wrote a thesis, naming it *Malta fever.* We medical *officers of the fleet called its slight cases* simple continued, its longer cases remittent. We thought it the same as we saw in military hospitals, though we felt those *were apt to be more serious and with worse rheumatism.* Bruce's discovery *of the M. melitensis* gave us a particular interest in it, but had not yet helped us to an ætiology or diagnosis.

Let us *go back to the cases. The Superb* in 1882 had the maximum, 234 cases in all, 70 invalidings, and 1 death. Part of her, the flying deck, was *overcrowded and ill-ventilated, and* was specially attacked—14 per cent., against 9 and 4 elsewhere.

In 1883 occurred the epidemic of "*Thalia* fever" on an overcrowded transport going to China. She had 479 men on board; a ship of her class would have had 250. She had about 80 cases, four invalids and no death. She reached Hong-Kong on the seventy-second day. Two cases *of erysipelas had been landed at Malta, three at Aden.* Her fever began at Colombo, eight landed at Singapore, ten on reaching Hong-Kong; *of these 18, 17 off the ill-ventilated lower deck.* The other cases developed in the *ships to which the men were sent; they did not infect* men of other ships. The fever had the facies of typhus. It was not infectious, and no one died, but it lasted dreadfully; *35 collected cases averaged 145·5* days under treatment, the chief sequela being *excruciating articular rheumatism.* Relapses were frequent. Surely this fever was due to want of ventilation, not to brucella septicæmia.

In 1884 the *Superb* returned 140 simple continued, and 124 remittent fever cases; *her medical officer claims that* improved ventilation has diminished incidence on the flying deck, but it still shows the highest *percentage.*

The *Alexandra* had in 1886 remittent fever cases 10 per cent. *of complement,* the *same in 1887, but in 1888 only* 3½ per cent. I put this down to better ventilation in 1888, when we *had always* a boiler alight drying the ship, and, as our stokehold was open, drawing the used *air* out of the lower part of the ship. In all that *commission* we had *no* case of brucella septicæmia in the wardroom; no one of us was long in hospital—the messman, yes, and the Admiral. In the mess I do not remember that we ever had porridge *for breakfast as in later years became a custom; we certainly did not drink milk as one heard officers did 10 to* 15 years later, when brucella septicæmia became prevalent; "officers one-third of cases" as a later Blue-book said.

The *Dreadnought,* in which I *served for two* months in 1888, had far more room for the men, and artificial ventilation, and little disease. In 1891 she reports how quickly influenza spread round her ship's company, but she was *then battened down owing to bad weather, and her auxiliary* natural ventilation was at an end. I would like to mention that in the same book it is reported that a case of simple continued fever in the *Australia* was invalided "owing to great debility and emaciation," which suggests meningococcal infection to me. Was this also with us in the Mediterranean and overlooked? The *Trafalgar,* turret ship with central battery, spoiling ventilation, reported 244 cases in 1891, but next year greater attention to ventilation (said her officers), and earlier leaving Malta (said her fleet surgeon) cut the number to 56.

Why are those cases continually ascribed to Malta by medical officers? It seems to be because Malta is the stuffiest harbour in the world. Shut in by the high fortifications, sheltered from slight breezes, doing special harm to stuffy ships. In the great *epidemic in the St. Jean d'Acre* in 1861, the temperature above the hammocks was noted as 81°, at which *temperature* expired *air stagnates*, and does not rise away from nor *fall from the breather.*[2]

My experience prejudices me to believe that fever in these ships long ago was due to poor ventilation. How precisely it produced effect I cannot say. I think chiefly by permitting dampness.

The driest ship I ever served in was the *Exmouth,* in the Channel in 1905–07. Weather was much the same, in January to March, in 1905 and 1906. She was better ventilated and drier the second year, and she had then far *fewer colds, as I had hoped.* One section, berthed lower than any other, had no colds at all. It alone had artificial ventilation, and housed the signalmen, who, "persecuting their vocation on the high and lofty bridge," as Kipling says, were most exposed *of all* men *to the* weather. I learned to pick signalmen out at quarters and musters by the notable redness of their lips, it may be said.

We want papers like *those Surgeon-Captain* Dudley has been good enough to put before us, but we also want studies of individual commissions of unhealthy ships, if any are left. Especially I would submit that rheumatism occurs as a sequela in other diseases than brucella septicæmia, and that future examinations must not depend on clinical diagnoses only when agglutinations, blood pictures, biochemical tests, &c., have become available for the elucidation of epidemics.—I am, Sir, yours faithfully,

---

Fleet-Surgeon.

Southborough, Kent, April 13th, 1931.

OVERCROWDING AS A FACTOR IN OUTBREAKS OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—To deal effectively with the points raised by Dr. Compton would take more space and time than is at my disposal. The incidence of cerebro-spinal fever or any other droplet-borne infection is doubtless dependent to some extent on indoor atmospheric humidity. But, even supposing the weight of this factor was generally less at sea than ashore, I cannot believe the difference in humidity was great enough to account for the great difference between the incidence of cerebro-spinal fever in the Navy afloat and ashore. Some of the facts on which I base this belief are:

(1) The carrier-rate was often as high in ships as in barracks.

(2) The high morbidity in ships of such droplet-borne infections as influenza and tonsillitis, which at times are as prevalent to-day when ventilation approaches perfection, as when ventilation was practically non-existent (as described in the third Milroy lecture).

(3) Cerebro-spinal fever has always been a rare naval disease. A search of the records of the Home Fleet for the 20 years 1860 to 1879 reveals only ten fatal cases of meningitis, in which middle-ear disease is not mentioned; seven of these were from boys in the training ships (average complement less than 3000). These numbers are, of course, very small, and it is hard to say if any, or all, of these cases were infected with *Neisseria meningitidis*. The reports however show, that meningitis was well recognised and described at the time, that it was rare at sea, that the mortality was 12 times as great in the training ships as in other ships, when the ventilation of both was bad, but equal.

To my mind (admittedly biased) the latent immunisation theory explains more *facts* in the epidemiology of cerebro-spinal fever than the indoor humidity theory. Both humidity and latently acquired immunity may have their share in determining the relative incidence of cerebro-spinal fever in the Navy ashore and afloat, but according to our respective experiences and prejudices I prefer to attach most weight to the latter, while Dr. Compton thinks humidity the more important factor.

I am, Sir, yours faithfully,
SHELDON F. DUDLEY.

Royal Naval Medical School, Greenwich, April 10th, 1931.

THE TERM HYPNOSIS.

To the Editor of THE LANCET.

SIR,—In my view the term basal hypnosis—as used, for example, in Dr. Magill's very interesting communication to THE LANCET for March 21st—is unsuitable and likely to cause confusion. The word hypnosis has its definite uses and applications which do not include reference to routine pre-anæsthetic sleep or quietude; anæsthetists must not run away with it for themselves. May I suggest that they try again?

I am, Sir, yours faithfully,
E. L. HOPEWELL-ASH.

Grosvenor-street, W., April 10th, 1931.

TREATMENT OF RHEUMATOID ARTHRITIS.

To the Editor of THE LANCET.

SIR,—In reply to Dr. Jenkins's courteous criticism published in your last issue (p. 835), I should like to make it clear that in condemning the use of vaccines, I referred to the simple suspensions, and made my objection on the grounds of absence of demonstrable specific effect. I agree, of course, that almost any form of vaccine may, if given in sufficient quantity in the late stage of rheumatoid arthritis, produce benefit by virtue of its action as a non-specific agent, and it is with this end in view that I give T.A.B. vaccine. Used in such a manner it is a matter of indifference whether focal sepsis has been found or not.

As to the question of a possible relationship between osteoarthritis and microbial activity, the more I see of the disease the more convinced I am that such relationship does not exist. Osteoarthritis is essentially degenerative in nature and commonly associated with hypothyroidism, rapidly increasing obesity, hyperpiesia, arterio-sclerosis, and/or a history of lifelong heavy manual labour. There is, I believe, something to be said for the view which I have expressed from time to time that the important ætiological factors are trauma and loss of vitality in varying proportion in each case.

I am, Sir, yours faithfully,
A. H. DOUTHWAITE.

London, W., April 13th, 1931.

POLYVALENT NATURAL ANTIBODY.

To the Editor of THE LANCET.

SIR,—In your last issue you published a letter from Dr. S. G. Billington who, after pointing out the vital importance that the antibody combinations known as Edwenil, Davenil, and Globenil should be accurately made and standardised, went on to state that he had no further association with the firm of E. H. Spicer & Co., Ltd., which had been offering these preparatio to the profession.

As this letter might be read as casting doubts on t reliability of products which are now being [illegible] factured and sold by my Company, I feel sure you [illegible] permit me to state that the preparation of Edwenil Davenil, and Globenil is being continued in laboratories at Watford, under precisely the [illegible] conditions as before. The manufacture of these antibodies is being carried out by expert chemists under medical supervision, and they are subjected [illegible] stringent tests which secure the highest possible standard of accuracy.

I am pleased to say that the numerous clinical reports received from medical men throughout the country continue to be uniformly satisfactory and show that Edwenil is of value in the entire range of endotoxic infections.

I am, Sir, yours faithfully,
E. H. SPICER,
Managing Director, E. H. Spicer and Co., Ltd.

Watford, Herts, April 13th, 1931.

THE LONDON VOLUNTARY HOSPITALS COMMITTEE.

To the Editor of THE LANCET.

SIR,—In your interesting account last week (p. 824) of the reception held at the Wellcome Historical Museum on March 26th you speak of Lord Macmillan as having acted as chairman of the "committee of relations between the voluntary and municipal hospitals in London." You are no doubt referring to the Voluntary Hospitals (Local Government Bill) Committee of the King's Fund, appointed by the Prince of Wales in January, 1929. Of this committee Mr. J. H. Whitley is chairman, and when he left for India Lord Macmillan was appointed vice-chairman. The committee published a memorandum on March 22nd of that year on the relations between voluntary hospitals and municipal hospitals under the Local Government Bill. This led to the appointment of a joint committee composed of representatives of the above committee, the conference of teaching hospitals in London, and the London Regional Committee of the British Hospitals Association, which prepared and published a scheme of voluntary hospital representation for the county of London under Sec. 13 of the Act. Lord Macmillan served on the joint committee as a representative of the King's Fund. The scheme was submitted to the London County Council and to the voluntary hospitals concerned, and obtained their approval, and the body thus constituted is now known as the London Voluntary Hospitals Committee, and is recognised by the London County Council as the body to be consulted by them under Sec. 13.

I am, Sir, yours faithfully,

E. A. H. JAY,

Secretary for Propaganda, King Edward's Hospital Fund for London.

April 13th, 1931.

RUSSIAN SCIENTISTS AT HOME.

To the Editor of THE LANCET.

SIR,—It is proposed to organise a tour of scientists to the U.S.S.R. and the first party will leave London Bridge by Soviet ship for Leningrad on July 18th. The return fare will be £18 inclusive. The party will spend a total of 16 days in Russia—three days in Leningrad, five days in Moscow, half a day in Nizhni-Novgorod and four days on the river down to Stalingrad (if desired) and the cost per day will be £1 per head inclusive—the balance of the days being spent in travelling. Meetings will be arranged which members of the party will be invited to address, and there will be excursions with guides to scientific institutions of interest to the members.

The Soviet authorities are prepared to give this tour second category accommodation at third category prices. The accommodation will be comfortable, and persons will sleep three or four in a room. Those wishing to sleep two in a room will pay five shillings per day extra. In the first instance the party will consist of 25 persons. If there is a large demand for places, a second party will be made up of 25; the Russian authorities are prepared to accommodate up to 100 persons if necessary. A further party may be arranged, if sufficient names are received, to leave London about the second week of August, returning to London in time for the British Association meeting.

The latest date for receiving applications is April 30th. Applications and all inquiries should be addressed to the Secretary, Society for Cultural Relations, 1, Montague-street, London, W.C.1.

We are, Sir, yours faithfully,

P. CHALMERS MITCHELL,
JULIAN HUXLEY,
E. C. SPRIGGE, *Chairman.*

April 8th, 1931.

OBITUARY

JAMES CAMPBELL HALL, M.B.Dub., D.L.

WE regret to announce the death of Dr. J. C. Hall, which took place after a short illness at his residence, Rowantree, Monaghan, on April 8th. He was born at Mourne Abbey, Kilkeel, Co. Down, in 1851, was educated at Dungannon Royal School, and took his medical course in Trinity College, Dublin, graduating in 1878. After spending some time in the asylum service he was appointed medical officer to the Scotstown dispensary district, and later physician to Monaghan County Fever Hospital. In 1890 he was appointed surgeon to Monaghan County Infirmary, a post he held for almost 40 years, and the operating theatre of which he equipped largely out of his own private purse. His skill was largely called upon by his medical colleagues as a consultant in the neighbouring counties.

Dr. Hall was a man of wide interests. He was a deputy-lieutenant for the county, a member of the grand jury, and took an active part in furthering the development of scientific farming among the agricultural community in which he lived. He was one of the most famous amateur rose growers in the country and was awarded by the National Rose Society, of which he was a vice-president, the Dean Hole Memorial Medal "in recognition of the meritorious services he rendered to the rose." He raised many new roses, five of which won the Gold Medal of the National Rose Society. Rose lovers will recognise the names of "Mrs. Campbell Hall" (named after his deceased wife), "Annie Crawford," "Muriel Wilson," "Julia Countess of Dartrey," and his latest success "Lord Rossmore."

In 1886 Dr. Hall contested the North Monaghan seat at Westminster in the Conservative interest but was unsuccessful.

THE LATE DR. CROZIER MAGEE.

Dr. Crozier Magee, whose death occurred a few weeks ago in a private hospital in Melbourne, Victoria, at the age of 71 years, had lived an interesting life. Born at Ballarat in 1859, he entered the service of the Bank of Australasia, and served in various towns in New South Wales. He resigned and took up pharmacy at Corowa, and on completion of his course travelled New South Wales and New Zealand for Messrs. Parke, Davis and Co., and introduced many drugs to the local medical profession. He then became pharmacist at the Brisbane Hospital (Queensland), where he met and married Nurse Rose Hardwicke. They settled at Wagga Wagga, N.S.W., where, and later at Albury, Dr. Magee held the position of superintendent, and Mrs. Magee that of matron. Dr. Magee then came to London and qualified in medicine from the London Hospital Medical School. On completing his course he made a voyage to Brazil as ship's surgeon in the cable ship *Dacia*. Returning to Australia in 1903, he practised in Penola, South Australia, until 1908, when after a voyage to China and Japan he bought a practice at Tungamah, Vict. Selling out in 1913 he made a voyage to Java, and on return served in the Commonwealth Government quarantine station at Sydney during the smallpox epidemic of that year. He then bought a practice at Branxholme, Vict., and remained there until the time of his death, his training and his great knowledge of drugs serving him in good stead. Dr. Magee leaves a widow and two sons.

PANEL PRACTICE

The London Public Medical Service.

FIGURES presented at the annual meeting of the Service made it clear that on the balance of gains and losses the number of subscribers has increased during the year by about 7 per cent., as much perhaps as could be expected when the class served is economically so depressed. The tendency to withdraw even in the winter months indicates there is a category of subscriber who joins for the purpose of securing treatment whilst ill and who discontinues as soon as normal health returns. It was suggested that membership is likely to gain in stability by attention to infant welfare. The central committee of the Service has taken pains to foster such work by issuing to members at cheap rates leaflets of instructions on breast-feeding, bottle-feeding, and feeding of weanlings. One member who started an infant welfare clinic on the committee's recommendation found it soon grow to considerable dimensions, with a resulting increase in the number of his subscribers. A mother who wants advice on how to keep her infant or her children well is a regular subscriber. With the help of the leaflets members of the Service can advise the whole family from the start, and forestall much childish illness. Such families are usually grateful and do not tend to drop out later.

The rates adopted in Kensington and Paddington have been found workable. In these areas the payment per week for a family of one member has been 4*d.* (or 6*d.*); of two members 8*d.*; of three members 11*d.*; of four or more members 1*s.* 1*d.* The yield per subscriber per week in Kensington is 3·96 *d.*, or after an administrative deduction of 25 per cent. 2·97 *d.*, distinctly more than the return in other areas on the older basis. A letter has been sent to individual members of hospital staffs, pointing out how their out-patient departments could be relieved of some of their work through the activities of the Service, with the avoidance of overlapping between specialists and general practitioners. As a result of this letter several consultants have become honorary members of the Service.

The Service is still not as well known as it might be, and the central committee is considering the question of publicity in the press. It seems specially desirable that insured persons who drop out of benefit should be aware of the advantages offered, and it has been the practice of some panel practitioners to send them notices drawing their attention to the Service. Since insured patients who are notified to their doctor as ceasing to be entitled to benefit nevertheless remain on his list until the end of the quarter, there is no possibility of such a notice being sent to any who are already on the list of another doctor. We may believe that the early difficulties in administering a new service of this kind are being surmounted and that the future is assured.

NATIONAL HOSPITAL, QUEEN-SQUARE.—A post-graduate course on diseases of the nervous system will be held at this hospital from May 4th to June 26th, consisting of clinical lectures and demonstrations at 3.30 P.M. each week-day, except Wednesday and Saturday, with out-patient teaching at 2 P.M. daily, except on Saturday, and pathological lectures at noon on Mondays. Clinical demonstrations, chiefly on methods of examination of the nervous system, will be given at 5 P.M. on Tuesdays and Thursdays, and, if there are enough applicants, lectures on anatomy and physiology at noon on Wednesdays and Fridays. Applications should be made to the Secretary, National Hospital, Queen-square, London, W.C.1.

MEDICAL NEWS

Royal College of Surgeons of England.

A meeting of the council was held on April 9th with L. Moynihan, the President, in the chair. The follo diplomas were granted:

F.R.C.S.—K. H. Pridie (Bristol and Guy's).

M.R.C.S.—Inez E. Banner (Punjab and Royal Free); Wi Dodd (Liverpool); and Margaret M. White (Royal Free).

L.D.S.—M. A. B. Brito-Mutunayagam.

The Diploma in Tropical Medicine and Hygiene w granted, jointly with the Royal College of Physicians, t the 30 candidates whose names were given on p. 783 of issue of April 4th.

Mr. G. E. Edington, of Glasgow, and Mr. E. F. Neve, Kashmir, being Members of 20 years' standing, were ele to the Fellowship.

The Jacksonian prize for 1930 was awarded to Mr. E. S. King, of Melbourne University, for his essay on the Patho of Ovarian Cysts and its bearing on their Treatment. Certificate of honourable mention for an essay on the sa subject was granted to Wilfred Shaw, St. Bartholome Hospital. For the year 1931 the subject for the Jack prize is the Surgery of the Sympathetic Nervous Sy and for the year 1932 the Pathology, Diagnosis, and Tre ment of Diverticula of the Large and Small Intestine. The John Hunter medal and triennial prize for 1928–30 w awarded to Mr. T. B. Layton, of Guy's Hospital, for contributions to otology, and for his valuable services the Museum, particularly in connexion with the O collection.—The Walker prize for work on the Patho and Therapeutics of Cancer for 1926–30 was awarded Sir G. Lenthal Cheatle.

The following was the Report of the Committee re mending the award.

> The work of Sir Lenthal Cheatle, continued over many ye and up to the present time, has been of great help to surgeons the elucidation and treatment of the precursory conditions cancer of the breast. It has shown that cancer is precede papillomatous hypertrophies chiefly affecting the smaller ducts particular lobes of the breast, and often associated with formation of cysts due to distension of the duct system. T methods employed have been laborious and systematic and ha correlated the microscopic and macroscopic anatomy of conditions studied. This has involved the making of wh sections of the breast by means of the giant microtome, an in ment of which this work has shown the great value. Committee consider that Sir Lenthal Cheatle has thus a definite and important contribution towards the solution of ætiological problem of cancer of the breast.

The Cartwright prize for 1926–30 was awarded to Dr. F. Broderick, L.D.S., of Bournemouth, for his essay on Ætiology, Pathology, and Treatment of Chronic Periodontitis (Pyorrhœa Alveolaris). The subject for Cartwright prize for 1931–35 is "The relationship of p teeth to general disease and their treatment with sp reference to periapical rarefaction."

Lord Moynihan was appointed the representative of College on the governing body of the British Post Hospital and Medical School to be established in Londo

University of London.

Forthcoming Lectures.—Dr. Otfrid Förster, professo neurology in the University of Breslau, will give lectures on Neurology at University College Hospital M School at 5.30 P.M. on April 29th and 30th, and on May He will deal with the results of electrical stimulation of cortex of the brain in man, and their relations to the re of experimental physiology, to architectonic structures, a to clinical symptomatology.—Two lectures on the Treat of Malignant Tumours by Radium Placed at a Distance be delivered by Dr. Max Cheval, of Brussels, at Westmins Hospital Medical School at 5.30 P.M. on May 4th and 5th. At the same hour on May 13th and 15th, at St. Thom Hospital Mr. G. Grey Turner, professor of surgery in t University of Durham, will give two lectures on Resecti of the Rectum.—Mr. Victor Cofman, D.Sc., will del three lectures, on the Biophysical Chemistry of Colloids a Protoplasm, in the Biological Theatre of King's Colle Strand, at 5.30 P.M. on May 4th, 11th, and 18th. The will be illustrated by experiments and lantern slides.

University College.—The annual dinner of the Fellows w be held at the College on Thursday, April 30th, at 7.15 f 7.30, with Sir John Rose Bradford, F.R.S., in the chair.

Red Cross Day.

May 12th, the anniversary of Florence Nightingale birthday, is to be celebrated this year as Red Cross Da throughout the Empire. A flag day will be held in Londo in aid of the funds of the British Red Cross Society.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

MINISTRY OF HEALTH VOTE.

THE House of Commons reassembled on Tuesday, April 14th, after the Easter recess. The House went into Committee of Supply on the Civil Service Estimates.

On a vote of £19,616,212 for the salaries and expenses of the Ministry of Health,

SICKNESS AND DISABLEMENT BENEFIT.

Mr. GREENWOOD (Minister of Health), in moving the vote, said that national health insurance had given a good deal of trouble. They were all aware of the increased expenditure of approved societies in recent years on sickness and disablement benefit. About a year ago the report of the Government-Actuary drew attention to these very disturbing facts. Since then a special Inter-Departmental Committee had been investigating this matter further. It was very difficult to assess the exact weight which should be given to the various factors causing this increase of expenditure on insurance benefit. He was not satisfied that there had been any substantial deterioration in the general health. There might have been here and there and in particular areas. It was largely due to the fact that there had been an expansion of additional benefit using up reserves created in earlier years, and partly, to what was right, that insured persons were taking full advantage of the rights which the law had conferred on them. It was very important that in the early stages of illness the insured person should go to the doctor and get the earliest possible treatment. But behind all legitimate causes, everyone associated with approved society work knew there was undoubtedly a certain amount of laxity. There could be no desire on the part of any non-member to deprive any sick person of what was properly due to him; on the other hand, there would be no difference of opinion as to the desirability of depriving people of benefit to which they were not entitled.

POSITION OF APPROVED SOCIETIES.

They were issuing to all approved societies memoranda which, he hoped, would be of some assistance in the matter of certification and supervision of claims for benefit. Last year the amount paid out in sickness benefit was £2,000,000 less than in the previous year. That was due to the fact that, 1930, on the whole, was a pretty good year as compared with 1929 in regard to sickness, and also partly, no doubt, to the fact that there had been some improvement in administration. The great increase in the expediture of societies in sickness and disablement benefit was naturally reflected in the financial conditions of the approved societies. They had now almost completed the third valuation of the approved societies. It would be found that the large majority of societies would still have disposable surpluses out of which they would be able to continue to pay additional benefits during the next five years. There were societies, however—and especially those who had separate funds for women, where the drain had been more than the average—whose disposable surpluses, unfortunately, had fallen to very small dimensions or had entirely disappeared. That was a serious problem which was now under very sympathetic consideration.

MATERNAL MORTALITY.

There could be no difference of opinion as to the seriousness of the problem of maternal mortality. They could not attempt to justify the death of 3000 mothers every year in the existing state of knowledge. It made motherhood by far the most dangerous occupation of this country, and the Departmental Committee on Maternal Mortality, appointed b Mr. Chamberlain three years ago, had examin these deaths and had arrived at results which serious. He could say, on the basis of the finding this Committee, that not less than one-half— might be more—of these maternal deaths preventable. That was a national scandal which public could not continue to tolerate. After consideration of the report he approached the local authoriti in a circular pointing out to them ways in which the might coöperate in this problem. At the end March he had received replies from 70 local authoriti Of these, 36 had adopted proposals for improvi their maternity services, while a number of others ha these matters still under their consideration. Fiftee authorities were establishing or extending their antenatal clinics; 10 were providing private practitioners for antenatal examinations; 12 wer improving their arrangements for the supply of midwives; 21 were arranging consultant services; were providing or extending hospital accommodatio and a number of others were arranging ancilliary services. Thus, in the three months sin the circular went out, there had been an earnes intention on the part of the local authorities t coöperate with the Ministry in an attack on th problem. He was keeping in touch with the lo authorities to see that, so far as was possible, t lived up to their responsibilities. Any scheme would involve the services of those authoriti The figures of maternal mortality for the past ye were about the same as for the year before.

TRANSFER OF POOR-LAW FUNCTIONS.

They could congratulate themselves on the smoothness with which the transfer of functions under th Local Government Act, 1929, had taken place. On of the purposes of the Act was to promote the up of the old poor-law system. On the whole having regard that only one year had elapsed, a g deal had been done in the direction of the break of the poor-law. Sixteen county councils and county borough councils had found it possible t make immediate declarations in their schemes. consisted of 24 by county borough councils under th Public Health Acts, 1 by a county council, and by county borough councils under the Deficiency Acts; 3 by county councils and 30 county borough councils under the Maternity Child Welfare Act; 10 by county councils, and 33 county borough councils, under the Blind Act; 3 by county councils, and 16 by county bor councils under the Public Health (Tubercul Act; and 9 by county councils and 41 by cou borough councils under the Education Act. T county borough councils had appropriated the poor-law institutions to Public Health Act purp 3 county borough councils had appropriated law institutions for Maternity and Child Welfare purposes, and 4 county councils and 1 county bor council had appropriated their poor-law institutio for purposes of the Mental Deficiency Act. London County Council had appropriated 27 poor-l institutions for the purposes of general hospitals an 10 for the purpose of children's hospitals convalescent homes.

POST-GRADUTE MEDICAL SCHEME.

During the past year they had improved in various ways the conditions under which local authorities might obtain loans. The amount of loans sanctioned had increased from £27,700,000 to nearly £47,500,000. The loans sanctioned for schemes for the relief of unemployment had increased from £1,300,000 to £14,400,000. As to the post-graduate hospital and medical school, his predecessor had presided over a committee, and it had been his privilege to complete that work. He believed that the post-graduate hospital and medical school was perhaps the biggest single step taken in this country in the interests of public health since the war, and he made no party capital out of it at all. When the report of the Committee came to hand he asked Lord Chelmsford to be chairman of an organisation committee to work out details. Those details had been worked out and they were now beginning the task of setting up the governing body of this institution. The Government were prepared to provide up to £250,000 for the actual building of the medical school and they would continue to make grants to the school. He hoped and believed that in the very near future the school and hospital would be actually at work and would exercise a very profound influence on the public health of the country.

Appointments

GRANT, J., M.B., Ch.B. Glasg., D.P.H., has been appointed Medical Officer for the Burgh of Ayr.

MCALISTER, W. M., M.B., Ch.B. Edin., Medical Officer in charge of Mental Health Services of the Edinburgh Corporation and Medical Superintendent of Bangour village.

PEEL, A. A. F., D.M. Oxf., to the Chair of the Practice of Medicine in Anderson College, Glasgow.

Royal Eye Hospital, St. George's-circus, S.E.: SAVIN, L. H., F.R.C.S. Eng., and SORSBY, A., F.R.C.S. Eng., Honorary Assistant Surgeons.

Vacancies

For further information refer to the advertisement columns.

Bangor, Caernarvonshire and Anglesey Infirmary.—H.S. £200. Also Hon. Surg.

Beckenham, Kent, Bethlem Hospital, Monks Orchard, Eden Park. Two Res. H.P.'s. Each at rate of £25 per quarter.

Birkenhead General Hospital.—H.P. £100.

Birmingham, Dudley-road, Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham Royal Cripples Hospital.—H.S. At rate of £200.

Birmingham, Selly Oak Hospital.—Res. Physician. £550.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.

Bradford Royal Infirmary.—H.P. and H.S. Each £150.

Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.

Brighton, Royal Sussex County Hospital.—H.P. £150.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Burton-on-Trent, County Borough.—Deputy M.O.H. &c. £600.

Burton-on-Trent General Infirmary.—Jun. H.S. £150. Also Sen. H.S. £200.

Cambridge, Addenbrooke's Hospital.—Res. Anæsthetist and Emergency Officer. Also H.S. Each at rate of £130.

Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.

Carlisle, Cumberland Infirmary.—Res. M.O. At rate of £155.

Chailey Heritage Orthopædic Hospitals.—Res. M.O. £200.

Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £150.

hild Guidance Council, 1, Canonbury-place, N.—Fellowships in Psychiatry. At rate of £150.

Ealing Borough.—Asst. M.O.H. £600.

nfield and Edmonton Joint Hospital Board, Winchmore Hill, N.—Res. Med. Supt. £700.

Gloucester, Gloucestershire Royal Infirmary, &c.—Second H.S. At rate of £120.

Great Yarmouth General Hospital.—H.S. £140.

Hellingly, East Sussex County Mental Hospital.—Jun. Asst. Res. M.O. £350.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Hove Borough, &c.—M.O.H. £1000.

Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.

Kingston-upon-Hull, City and County of.—Asst. Tub. Officer. £600.

Leicester Royal Infirmary.—Two Surgical Dressers. 10*s.* 6*d.* per week.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, City of.—M.O. £1800.

Liverpool, Eye and Ear Infirmary.—H.S. to Ophth. Dept. £100.

Liverpool, Royal Children's Hospital.—Res. H.S. At rate of £100.

Macclesfield, Cheshire County Mental Hospital, Parkside.—Asst. M.O. £350.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Manchester and Salford Hospital for Skin Diseases.—H.S. At rate of £100.

Manchester, Royal Children's Hospital, Pendlebury.—Res. Surg. O. At rate of £125.

Manchester, Royal Infirmary.—H.S. for Central Branch, Roby-street. At rate of £100.

Manchester Royal Infirmary.—Res. Surg. O. £200.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Two Res. Anæsthetists. Each at rate of £200.

Northampton General Hospital.—Hon. Surgeon.

Nottingham City Infirmary, Bucknall-road.—M.O. £350.

Nottingham General Hospital.—H.S. and H.P. Each at rate of £150.

Oldham Royal Infirmary.—H.S.'s to Special Depts. Each at rate of £175.

Pendleton, Hope Hospital.—Asst. Res. M.O. At rate of £250

Poplar Hospital for Accidents, East India Dock-road, E.—Sen. Res. O. £200.

Preston, County Mental Hospital, Whittingham.—Med. Supt. £950.

Queen's Hospital for Children, Hackney-road, E.—2 H.P.'s. Each at rate of £100. Also Cas. O. At rate of £100.

Radium Institute, Riding House-street, W.—H.S. At rate of £150.

Robertsbridge, Sussex, Darwell Hall Sanatorium.—Surgeon for Ear, Nose and Throat. 3 guineas per visit.

Rochdale Infirmary and Dispensary.—Senr. H.S. At rate of £250.

Rotherham Hospital.—H.P. £180. Cas. H.S. £120. Hon. Surgeon to Ear, Nose and Throat Dept. Also Hon. Dental Surgeon to Out-patients' Depts.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. and Asst. H.S. At rate of £150 and £100 respectively.

Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £150. Also Asst. Surgeon and Asst. Surgeon to Ear, Nose, and Throat Dept.

Royal Northern Hospital, Holloway, N.—Res. Out-patient Cas. O. and Anæsthetist. At rate of £70.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. for Out-patient Dept. £150.

St. Helens Hospital.—H.S. £200.

St. John's Hospital, Lewisham, S.E.—Res. H.S. At rate of £100.

St. Marylebone General Dispensary, 30, Marylebone-lane, W.—Hon. Surgeon to Ear, Nose, and Throat Dept.

Samaritan, Free Hospital for Women, Marylebone-rd.—H.S. At rate of £100.

Scunthorpe and District War Memorial Hospital.—Second Res. Surgeon. £150.

Stafford, Staffordshire General Infirmary.—H.P. At rate of £150.

Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Asst. Surgeon.

Sunderland, Durham County and Sunderland Eye Infirmary.—Two H.S.'s. Each £350.

Swansea General and Eye Hospital.—Cas. O. £200.

Taunton, Taunton and Somerset Hospital.—H.P. £100.

Wallasey Victoria Central Hospital.—Jun. H.S. At rate of £100.

Walsall General Hospital.—H.S. At rate of £150.

Warrington Infirmary and Dispensary.—Anæsthetist. £150.

Wigan Infirmary.—H.S. At rate of £150.

Wrexham and East Denbighshire War Memorial Hospital.—Res. H.S. At rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Mitcheldean (Glos.); New Galloway (Kirkcudbright); and at Poulton-le-Fylde (Lancs).

Births, Marriages, and Deaths

BIRTHS.

ARCHER.—On April 6th, at Lorna Lodge, Didsbury, Manchester, the wife of Dr. George Eric Archer, of a daughter.

LOWE.—On April 8th, the wife of John Burman Lowe, M.B., Ch.B., Lacock, Wilts, of a son.

MARRIAGES.

ADAMSON—SANDERSON.—On April 8th, at Cramond Church, Midlothian, William A. D. Adamson, M.B., to Lilian D. B. Sanderson, daughter of the late Mr. and Mrs. W. M. Sanderson, "Winton," Cramond Bridge.

DAGGER—DAVIES.—On April 11th, at St. Michael's, Eastbourne, Thomas Dagger, L.D.S., M.R.C.S., L.R.C.P., to Joan Lamprell, second daughter of Mr. and Mrs. Herbert Davies, of Eastbourne.

JOHNSON—COUTTS.—On April 2nd, at Bowness-on-Windermere, Athol J. Johnson, M.B., Ch.B., Colonial Medical Service, to Dorothy Gordon, younger daughter of Dr. F. J. H. Coutts, C.B., and Mrs. Coutts, of Bournemouth.

DEATHS.

BEVIR.—On April 13th, at a nursing home in Clifton, George Bevir, M.R.C.S., L.R.C.P., of Timsbury, near Bath, in his 52nd year.

HALL.—On April 8th, at Rowantree, Monaghan, after brief illness, James Campbell Hall, D.L., M.B.

WOODHOUSE.—On April 10th, at the house of his son-in-law, Lord Kingsale, in Devon, Major-General Sir Tom Percy Woodhouse, late R.A.M.C., in his 74th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

FELLOWSHIP IN PSYCHIATRY.—It is announced in our advertisement columns that the Child Guidance Council is offering one or two Fellowships in psychiatry, tenable at the London Child Guidance Clinic, to registered medical practitioners who hold the D.P.M. or have had suitable experience. The value of the Fellowship will be not less than £150 for six months' training.

NOTES, COMMENTS, AND ABSTRACTS

HOMER'S SURGEONS: MACHAON AND PODALIRIUS.

By S. Wood.

(From the Library, Royal College of Surgeons of England.)

Part I.

When the inconstant Helen of Troy deserted her husband to go with Paris she inspired the *Iliad* of Homer, which reveals to us the state of Greek medicine 3000 years ago. The passages of medical interest occurring in this graphic story have been so carefully annotated by Daremberg[1] and others that a further study of them would be superfluous. My purpose is to gather the scattered fragments relating to Machaon and Podalirius, the sons of Æsculapius and the "Fathers of Surgery," who were the chief medical officers attached to the Greek forces during their battles against the Trojans. They were valiant warriors as well as surgeons, and commanded 30 ships of the fleet that sailed to the siege of Troy:

> From Tricca, from Ithome rough and rude
> With rocks and glens, and from Œchalia, town
> Of Eurytus Œchalian-born, came forth
> Their war-like youth by Podalirius led
> And by Machaon, healers both expert
> Of all disease, and thirty ships were theirs.[2]

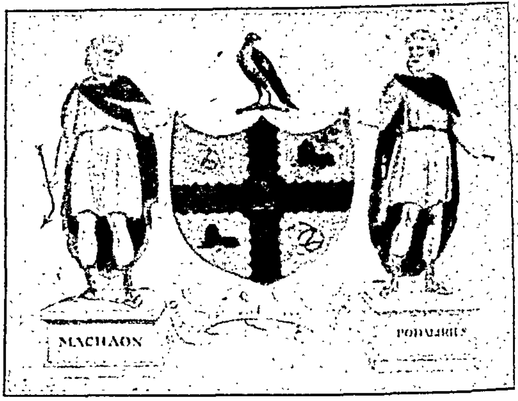
Gordon[3] says that the siege of Troy, and circumstances that led to it, are looked upon as but a western version of the events related in the Ramayana, the great epic of the Hindoos. Schliemann[4] and his colleague Dörpfeld,[4a] however, have demonstrated by their excavations at the site of ancient Troy that the *Iliad* is not a phantasy but a narration of events that occurred about 1200 B.C., and our two characters figure in the *Iliad* and other ancient writings in proof of their existence, though their reputed genealogy does not inspire the same confidence. They were supposed to be the sons of Æsculapius, the God of Medicine, but Renouard[5] believes that this description was used in a figurative sense and applied generally to men who devoted themselves to the practice of medicine. It is possible, however, that they were sons of Æsculapius, for contrary to the belief that he was a mythological character and not a real personage is the evidence of Homer and Pindar, who speak of him as a man. His memory was held in the very highest regard by the Greeks, by whom he was publicly deified at Athens in 420 B.C.[6] and in whose honour they erected temples, the Asclepieia, where his healing powers might be perpetuated for the benefit of succeeding generations.

The Two Brothers.

Machaon is usually referred to as the elder of the two brothers, and this is supported by Quintus Calaber's account of the death of Podalirius, who said "his dear brother had brought him up like a son after their father was taken into Heaven and that he had taught him to cure diseases."[7] Homer always names Podalirius first when he mentions the brothers together, but on this point the old historian Le Clerc[8] says "'tis only for the convenience of his Metre." Troy was taken by the Greeks 1184 B.C.,[9] and as Machaon was at that time a fully-fledged warrior it follows that he was born between 1219 and 1209 B.C. if we assume the age of such a man to be from 25 to 35 years. Both he and his father are said to have been born at Tricca in Thessaly, Æsculapius being a Thessalian prince and sovereign of the towns of Tricca and Œchalia. Nothing further is known of Machaon until he is introduced by Homer as a leader of troops and healer of disease.

Arctinus[10] (775–740 B.C.) says "the brothers were endowed with precious gifts. To Machaon was given delicate hands for drawing traits from the skin, to sew up and cure all wounds." The healing of Philoctetes' poisoned foot is adduced as an instance of his great skill, which was superior even to that of Chiron, his father's teacher, whose treatment failed in a similar case. Unfortunately there is little record of their work save the extraction of arrow and spear-heads, checking hæmorrhage by styptic preparations, and the applying of soothing ointments to wounded and bruised surfaces. No mention is made of amputations, setting of fractures, or tying of arteries.

The brothers, although called by Homer "healers of all disease," were powerless against the plague which attacked the Greek troops, and which is so well described at the opening of the *Iliad*. The sickness was attributed to the arrows of an angry god and it attacked horses, dogs, and men alike. After nine days, during which the funeral pyres burned continually, a council was held to consider what might be done. A captive maid was released to appease the wrath of the god, and the pestilence thereafter abated. With regard to this plague a modern note is struck by Dr. Edgeworth,[11] who suggests that the disease in question was dysentery, which has been endemic in the Mediterranean basin since prehistoric times—during the Great War the disease was terribly destructive in Gallipoli.



The Arms of the Corporation of Surgeons of London, showing as supporters Machaon on the left and Podalirius on the right.

An Arrow Wound.

There is an urgent call for Machaon when Menelaus is wounded in the side by an arrow treacherously shot by Pandarus. The wounded man makes light of his injury to Agammemnon, his brother, who is sighing over him, and says, "Be of good courage. The keen dart lighted not upon a deadly spot." Agammemnon replies, "Would it may be so, Menelaus. . . .

> But the hand of one
> Skilful to heal shall visit and shall dress
> The wound with drugs of pain-assuaging power,
> He ended, and his noble herald, next
> Bespake, Talthybius 'Haste, call hither quick
> The son of Æsculapius, leech renown'd
> The prince Machaon. Bid him fly to attend
> The war-like Chieftain Menelaus' . . . .
> He spake, nor him the herald disobey'd,
> But through the Greeks bright-arm'd his course began.
> The hero seeking earnest on all sides
> Machaon. Him, ere long, he stationed saw
> Amid the shielded-ranks of his brave band
> From steed-famed Tricca drawn, and at his side
> With accents ardour-wing'd, him thus addressed
> 'Haste, Asclepiades. The king of men
> Calls thee. Delay not. Thou must visit quick
> Brave Menelaus.'"[12]

Machaon hastens to his patient who stands surrounded and pressed upon in the manner of to-day by sympathetic and curious onlookers. Moreover, the crowd consists of select people "the bravest of Achaia's host," and in view of this formidable audience of chiefs Machaon proceeds to demonstrate his skill upon the unfortunate Menelaus.

. . . . he strove at once
To draw the arrow from his cincture forth,
But, drawing, bent the barbs. He therefor loosed
His broider'd belt, his hauberk and his quilt,
Work of the armourer, and laying bare
His body where the bitter shaft had plow'd
His flesh, he suck'ed the wound, then spread it o'er
With drugs of balmy power, given on a time
For friendship's sake by Chiron to his sire."[13]

Machaon's hasty and forcible treatment resulted in damage to the arrow, but owing to diverse translations it is difficult to determine what actually occurred. Cowper says that Machaon in drawing "bent" the barbs. Others render the word "broken," while Chapman[14] translates the line "which forth he brings without the forks." The last translation appears the least reliable; Machaon, the surgeon-general, would not have applied "drugs of balmy power" to heal the tissues over the barbs of an arrow—unless he had in mind the performance of a "two-stage" operation. There is a difference of opinion, too, regarding the treatment of the wound. *Machaon is said by some to have sucked out the* blood, but the argumentative Le Clerc[15] takes exception to this translation, and says, "He dressed Menelaus . . . wiping first the blood from the wound and not sucking it with his lips as a certain learned man, misled by the nearest signification of the word that Homer uses, has written." Eloy[16] and Portal[17] follow him, but these are clearly copying Le Clerc's words. Malgaigne[18] draws attention to the interesting point that Machaon must have carried dressings with him on the battle-field, for when *summoned by the herald he at once left his men and,* without returning to his tent, made his way to where the stricken King of Sparta awaited his ministrations.

Machaon Himself Injured.

The next incident concerns the wounding of Machaon himself. While fighting valiantly an arrow pierced his right shoulder, to the great dismay of the Greeks, who fought furiously around the wounded man to prevent him from being taken and killed by the enemy.

Not even then had the bold Greeks retired,
But that an arrow triple-barb'd dispatch'd
By Paris, Helen's mate, against the Chief
Machaon warring with distinguished force,
Pierced his right shoulder. For his sake alarm'd,
The valour-breathing Grecians fear'd, lest he
In that disastrous field should also fall.[19]

Nestor is called upon to take the wounded man into his chariot and, with all despatch, bear him out of the battle to a place of safety.

At once, Idomeneus of Crete approach'd
The noble Nestor, and him thus bespake.
"Arise Neleian Nestor! Pride of Greece!
Ascend thy chariot, and Machaon *placed*
Beside thee, bear him, instant, to the fleet,
For one, so skill'd in medicine, and to free
The inherent barb, is worth a multitude."
He said, nor the Geranian hero old
Aught hesitated, but into his seat
Ascended, and Machaon, son renown'd
Of Æsculapius, mounted at his side.
He lash'd the steeds, they not unwilling sought
The hollow ships, long their familiar home.[20]

The interest in Machaon's wound extends even to the great Achilles, who sends Patroclus hot-foot to ascertain if the injured man is indeed Machaon.

"The mares of *Nestor* all sweating bare him out of the battle, and also carried they Machaon, shepherd of the host. Then the noble Achilles beheld and was aware of him. And straightway he spoke to his own comrade, 'Go now, Patroclus, and ask Nestor who is this that he bringeth wounded from the war. Verily from behind he is like Machaon, that *child of* Asklepios, but I beheld not the eyes of the man, for the horses sped past me, straining forward eagerly.'"[21]

The chariot arrives at Nestor's hut where they receive the attention of the fair-tressed Hekamede, a chieftain's captive daughter, and a "nymph of form divine," who, in spite of her youthful appearance, seems to have been an apothecary, for she is credited with understanding the virtues of the herbs of all the earth, a considerable accomplishment in one so young.

Now when Neleian Nestor to his tent
Had brought Machaon, they alighted both.
. . . . On the beach awhile
Their tunics sweat-imbued in the cool air
They ventilated, facing the full breeze,
Then *on* soft couches in the tent reposed.
Meantime, their beverage Hekamede mix't . . .
She, first, before them placed a table bright
With feet caerulean; thirst provoking sauce
She brought them also in a brazen tray,
Garlick and honey new, and sacred meal.
Beside them, next, she placed a noble cup . . . .
The graceful virgin in that cup a draught
Mix'd for them, Pramnian wine and savoury cheese
Of goat's milk, grated with a brazen rasp,
Then sprinkled all with meal. The draught prepared
She gave it to their hand; they drinking, slaked
Their fiery thirst, and with each other sat
Conversing friendly . . . ."[22]

Machaon's wound was evidently not of a serious nature, *for nothing appears to have been attempted* in the way of treatment. The narrative relates that the patient and Nestor sat in friendly converse, which says much for Machaon's fortitude if he was seriously hurt. Patroclus, too, on his arrival at the tent, did not offer his help as he certainly would have done in a case of urgency, since on another occasion he was sufficiently skilful as a surgeon to treat Eurypylus by enlarging a wound with his knife in order to release an embedded weapon.[23] It may be that he considered the older and wiser Nestor to be equal to the occasion. Nestor, however, becoming uneasy at the increasing noise of battle, leaves the captive maid in charge of Machaon to whom he says, "*Bethink thee, noble Machaon,* what had best be done, lo, louder waxes the cry of the strong warriors by the ships. Nay, now sit where thou art, and drink the bright wine, till Hekamede shall heat warm water for the bath, and wash away the clotted blood, but I will speedily go forth and come to a place of outlook."[24]

Machaon. (Reproduced from the Sambuci book of portraits published at Amsterdam in 1612.)

A Strange Potion.

The curious mixture of wine, grated cheese, and barley given to the wounded has been subjected to a great deal of criticism, much of it adverse. Plato[25] decided against it saying that the draught was of an inflammatory nature and a strange potion to give to a wounded man, but with the reservation that the remedies of those days were intended for people of sound constitutions and not for those labouring under chronic affections, who evoked but little sympathy. Villoisin in his Scholia considers that these substances *presented* to Machaon, "the wounded offspring of the healing god," were viewed less as remedies than as refreshments necessary in consequence of his fatigue, and a similar observation is made by Eustathius in his commentaries on the works of Homer. Malgaigne[26] says that not sufficient distinction is made between the state of the recently wounded and the entirely different condition of an injury complicated by traumatic fever; he recalls that Larrey, the great French military surgeon, who gave wine to his wounded, even to those suffering amputation, was unconsciously a follower of the school of Machaon. According to Berdoe,[27] Homer's physicians were in the right. Good old wine was the best thing possible to restore a man fainting from loss of blood; as for the cheese, it was grated fine and therefore was a particularly nutritious food in a fairly digestible condition. As though the question were a debatable one even at the time of Troy, the following unsympathetic judgment is attributed to the brothers. "If the men are sound," they said, "wine and cheese will not hurt them; if they are not, let them die and make room for better men."[28]

Vergil[29] and others relate that Machaon entered Troy in the Wooden Horse, the town being taken immediately the occupants were released from that structure. In Dryden's translation of the Aeneid, however, it is not Machaon but his brother who was amongst the warriors concealed in the Wooden Horse. When the Greeks sailed away in their ships, pretending to abandon the siege, they left behind a huge wooden building which held a band of armed men who, under cover of the darkness, were to be released by Sinon, the spy. Although a spear thrust through its wall elicited groans from within, the Trojans, "blinded by their fate," dragged the "horse" inside the city gates and so accomplished their own destruction.

When Sinon, favoured by the partial gods,
Unlocked the horse and oped his dark abodes,
Restored to vital air our hidden foes,
Who joyful from their long confinement rose
Tysander bold, and Sthenelus their guide,
And dire Ulysses down the cable slide;
Then Thoas, Athamas, and Pyrrhus haste,
Nor was the Podalyrian last.[30]

Le Clerc[31] appears to be in error when he says that Machaon cured the lame Philoctetes on his return from Troy. Philoctetes, a Thessalian prince, was amongst those who sailed to make war against the city of Troy. During the voyage he and his companions landed on the island of Chrysa to see the altar of Athene, but Philoctetes, approaching it too closely, was bitten in the foot by the guardian serpent. The pain of his injury troubled him day and night, and the offensive nature of the wound caused the Greeks to leave him on the sacred island of Lemnos when the voyage was resumed. Ten years elapsed and the soothsayers said that Troy could not be taken until the great archer Philoctetes and the arrows given to him by Hercules should be brought against it. The crafty Ulysses and others were sent to fetch him but he refused to help those who had formerly deserted him. In spite of persuasion and attempts to steal the famous arrows, he clung to his decision until Hercules appeared to him in a supernatural manner and said, "Thou shalt go to the land of Troy, and first thou shalt be healed of thy grievous sickness, and afterwards thou shalt slay Paris with thine arrows, and shalt take the city of Troy." To Achilles he said, "Thou canst not take the city of Troy without this man, nor he without thee."[32]

Quintus Smyrnaeus[33] thus imagines the scene at the healing of Philoctetes by Podalirius:—

Men beheld, and all
Compassionated that great archer, crushed
By anguish of his hurt. But one drew near,
Podaleirius, godlike in his power to heal.
Swifter than thought he made him whole and sound;
For deftly on the wound he spread his salves,
Calling on his physician-father's name;
And soon the Achaans shouted all for joy,
All praising with one voice Asclepius' son.
Lovingly then they bathed him, and with oil
Anointed. All his heaviness of cheer
And misery, vanished by the Immortals' will;
And glad at heart were all that looked on him;
And from affliction he awoke to joy.
Over the bloodless face the flush of health
Glowed, and for wretched weakness mighty strength
Thrilled through him: goodly and great waxed all his limbs
. . . . So Philoctetes' erstwhile wasted frame
Was all requickened.

His recovery was so complete that he was able to slay Paris as foretold by Hercules.

The Death of Machaon.

There is the usual conflict of opinion regarding the fate of Machaon. Apollodorus[34] relates that Panthesilia, daughter of Otrere and Ares, slew many in battle and amongst them Machaon. Pausanias[35] writes that he was killed in single combat in front of Troy by Nireus, or, according to others, by Eurypylus, and was buried in Messenia whither his remains were removed by the care of Nestor and preserved as sacred relics. Quintus Smyrnaeus[36] who perhaps had before him the works of the Cyclic poets, which have since been lost, records in a graphic way the manner of Machaon's death at the hand of Eurypylus. In a general battle before Troy Nireus has just slain by Eurypylus, against whom Machaon turns to avenge his friend:—

With his spear he drave
At his right shoulder: strong albeit he was,
He touched him, and blood spurted from the gash.
Yet, ere he might leap back from grapple of death,
Fierce Eurypylus on Machaon rushed.
The long lance shot out swiftly, and pierced him through
On the right haunch; yet would he not give back,
Nor flinch from the onset, fast though flowed the blood.

In haste he snatched a huge stone from the ground,
And dashed it on the head of Telephus' son;
But his helm warded him from death or harm.
Then waxed Eurypylus more hotly wroth
With that strong warrior, and in fury of soul
Clear through Machaon's breast he drave his spear,
And through the midriff passed the gory point.
He fell, as falls beneath a lion's jaws
A bull, and round him clashed his glancing arms.

Swiftly Eurypylus plucked the lance of death
Out of the wound, and vaunting cried aloud:
Faint-breathing answered him the dying man,
"Eurypylus, thine own weird is to live
Not long: Fate is at point to meet thee here
On Troy's plain, and to still thine impious tongue."
So passed his spirit into Hades' halls.

Then to the dead man spake his conqueror:
"Now on the earth lie thou. What shall betide
Hereafter, care I not—yea, though this day
Death's doom stand at my feet. No man may live
For ever: each man's fate is preordained."

Teucer, a Greek leader, on seeing Machaon's fall urges his men to greater deeds in order to prevent the body falling into the hands of their enemies:

With a great voice he raised the rescue-cry:
"Charge, Argives! Flinch not from the charging foe!
For shame unspeakable shall cover us
If Trojan men hale back to Ilium
Noble Machaon and Nireus godlike-fair."

The rescue caused a host of men to die on either side in the desperate fighting that ensued, but at last the few Danaans who survived bore the bodies back to the ships.

News of his brother's fate is brought to Podalirius who is hard at work dressing the injuries of the struck down in the battle. The merciful surgeon transformed into a relentless avenger:

He clad him in his armour. For conflict grim
He panted: boiled the mad blood round his heart
He leapt amidst the foemen; his swift hands
Swung the snake-headed javelin up, and hurled,
And slew with its winged speed Agamestor's son
Cleitus. Then by his warrior-brother laid he low
Lassus . . . .

Next morning death-dues were rendered to the fallen. The Greeks mourned over the grave for Nireus, and for Machaon

whom they honoured aye,
For his deep wisdom, as the immortal gods.
One mound they swiftly heaped above these twain.
Then in the plain once more did murderous war
Madden.

Podalirius is distracted with grief, and seeks to slay himself with his sword but is restrained by friends. He is looking amongst his herbs for a deadly drug when Nestor appears with words of comfort:

"Refrain from bitter moan and deadly grief,
My son. It is not for a wise man's honour
To wail, as doth a woman, o'er the fallen.
His end was worthy his life
Endure thy sore grief, even as I endured,
Who lost a son, a mortal man must bear
All joys, all griefs, that God vouchsafes to send"

Made answer the heart-stricken one, while still
Wet were his cheeks with ever-flowing tears :
‘ Father, mine heart is bowed 'neath crushing grief
For a brother passing wise, who fostered me
Even as a son. When to the heavens has passed
Our father, in his arms he cradled me ;
Gladly he taught me all his healing lore ;
We shared one table ; in one bed we lay.
We had all things in common—these, and love
My grief cannot forget, nor I desire,
Now he is dead, to see the light of life."

Then spake the old man to the stricken one :
" To all men Fate assigns one same sad lot,
Bereavement : All happy is no living man
From the beginning to the end our life is short
Beseems not then in grief to live. Hope on,
Still hope for better days ; chain not to woo
Thine heart. There is a saying among men
That to the heavens unperishing mount the souls
Of good men. Both to God and man
Dear was thy brother, good to brother men,
And son of an Immortal. Sure am I
That to the company of gods shall he
Ascend, by intercession of thy sire."

Then raised he the reluctant mourner up
With comfortable words. From that dark grave
He drew him, backwards gazing oft with groans,
To the ships they came.

Lesches, the author of the epic called the " Little Iliad " also says that Machaon was killed by Eurypylus, son of Telephus. That is why the following rule was observed in the sanctuary of Æsculapius at Pergamus. Though they began the hymns with Telephus they aid not a word about Eurypylus in them ; indeed, hey would not even name him in the temple because hey knew that he was the murderer of Machaon.[37]

Rival Versions of the Story.

Sprengel [38] has a different and less tragic story to ell. His version is that Machaon survived the Trojan war and passed the remainder of his life in Messenia with or near the sage Nestor. In this country he founded two towns bearing the same names as those of which his father had been sovereign, Tricca and Œchalia. His wife was Anticlea, daughter of Diocles, King of Messenia, and by her he had two sons, Nicomachus and Gorgamus, who resided at Pheræ and possessed the kingdom of their grandfather till the Heraclians, on their return from Troy, made themselves masters of Messenia and the rest of Peloponnesus, whence they drove both them and others. Pausanius mentions some other sons of Machaon, as Sphyrus, Alexanor, and Polymocrates, who followed their father's profession which was carefully preserved in the family. The same author questions whether Machaon was a king in his own right or by virtue of his marriage, but Homer calls him a " Pastor of the People " which is the title he gives to Agammemnon and other kings. The consternation of the Greeks when he, " leader revered," was wounded, also proves that he was a person of great importance.

Other classical writers have followed Homer in eferring to Machaon. Ovid [39] mentions him in the first book of *De Ponto*,

Utque Machionlis Poeantius atibus heros.

and in the third book,

Firma valent per se, nullumque Machaona quaerunt.

Martial [40] also brings his name in a general manner into the following passage :

Zoilus aegrotat, faciut hac stragula febrem
Si fuerit sanus, coccina quid faciet ?
Quid thorus a nilo. Quid sidone tinctus olenti
Ostendit stultas quid nisi morbus opes ?
Quid tibi cu Medicis demicte Machaonas ones
Vis fieri sanus ? Stragula sume mea.

His memory is perpetuated in science in *Papilio Machaon*, the name applied to the swallow-tailed butterfly.

A USEFUL SAINT.

To the Editor of THE LANCET.

SIR,—" Etymologist " asks (page 842) who was Saint Acaire. He was a bishop of Noyon, who died in 630 (A.D., of course). His relics are credited with the virtue of curing those of soured temper. *Avoir le mal de Saint-Acaire* is to be sour, cross-grained, difficult, cranky, but not, I think, mad or insane. The *fête* of the saint is the twenty-seventh of November. I am, Sir, yours faithfully,

April 10th, 1931. F. G. C.

To the Editor of THE LANCET.

SIR,—" Etymologist " may be interested to know that Brachet in his " Dictionnaire étymologique de la langue française " shows the etymology of acariâtre as " unknown." Probably the Saint Acaire of Larousse is as mythical as most other saintly curers of disease. I am, Sir, yours faithfully,

April 10th, 1931. A. G. C.

THE MODERN PARENT CRITICISED.

A BOOK[1] dedicated by its author " To my three children . . . whom I have often annoyed," deserves attention. Dr. Myers proceeds to describe with faithfulness and humour the many ways in which parents may irritate their offspring. He addresses himself to parents directly, using colloquial language and avoiding pseudo-scientific terminology. Unlike many psychologists he does not utterly condemn corporal punishment, and even deplores the difficulties of a mother compelled to administer all the slaps herself owing to lack of coöperation on the part of the father. He makes good use of the emphasis to be obtained by repeating his opinions and observations in several ways. Nor is his sympathy confined wholly to the child ; doubtful of the effects of his salutary criticism on the morale of parents he ends many of his chapters by exhorting them to count their successes rather than their failures, and to remember that their motives were above reproach. His investigations of problem parents cover those who are discourteous, quarrelsome, scolding, or inconsistent, those who make the social graces painful to their children, who act childishly towards them, who teach them to lie or tempt them to steal, and those who play upon the emotions of the child until he becomes callous in self defence.

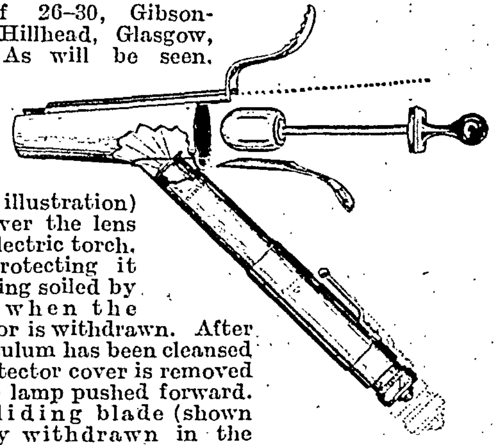
[1] The Modern Parent: A Practical Guide to Everyday Problems. By Garry Cleveland Myers, Ph.D., Head, Division of Parental Education, Cleveland College, Western Reserve University. London: Williams and Norgate, Ltd. 1930. Pp. 350. 8s. 6d.

ELECTRIC RECTOSCOPE.

AN improved form of speculum for use in rectal diagnosis and in the injection treatment of hæmorrhoids has been placed on the market by Messrs. John Smith and Son, of 26–30, Gibson-street, Hillhead, Glasgow, W. 2. As will be seen, a protector cover (shown withdrawn in the illustration) slides over the lens of the electric torch, thus protecting it from being soiled by fæces when the obturator is withdrawn. After the speculum has been cleansed the protector cover is removed and the lamp pushed forward. The sliding blade (shown partially withdrawn in the illustration) is then wholly withdrawn, and the wall of the anal canal and rectum is thus exposed through the whole length of the speculum. The tube carrying the electric bulb and battery is fitted with a switch which permits the light to be kept on continuously or cut off as required, while the torch is detachable so that the instrument may be sterilised.



NEW PREPARATIONS.

KOLA ASTIER (P. Astier Laboratories, 41–47, Rue du Docteur-Blanche, Paris. Agents, Messrs. Wilcox, Jozeau and Co., 15, Great St. Andrew-street, London, W.C.).—Samples of this preparation are being distributed to the medical profession with a description of the chemical composition, when the claim made for it that it forms a good general tonic is substantiated by all pharmacological inquiry into the caffeine content of kola. The cardiotonic action of the drug is the property to which special attention is drawn in recommending its employment in chronic nervous disorders, convalescence after long illness, or premature senile changes.

From the same firm we have received a sample of ARHÉOL, a preparation of sandal wood, for use in gonorrhœa and vesicular disorders. Care has been taken to use a very pure and therefore active sandal-wood oil, producing a balsamic of constant composition which is made up in capsular form.

We have received also from the Astier Laboratories samples of COLITIQUE, an anticolibacillary vaccine, and STALYSINE, an antistaphylococcic vaccine, both of which are prepared according to the technique of Dr. Fisch. To the value of these preparations a certain amount of medical support is forthcoming, and it may be noted, as evidence of care on the part of the firm, that the date of manufacture is in each case stated on the containing boxes, with the warning that the preparations are not guaranteed to remain active for more than two years.

VIODAR (Mr. W. Martindale, 12, New Cavendish-street, London, W.) is an oily preparation containing free iodine, to which the violet colour is due, and is made in two strengths, 1 in 1000 and 1 in 200, for external and internal use. While the standardised proportions of iodine in oily combination are present, the contents are stable in stoppered bottles at ordinary temperatures, the iodine being liberated at the temperature of the body. Preparations of iodine are liable to turn acid, and are then not tolerated by all subjects, a particular susceptibility having often been noted, but the manufacturer has reason to believe that this trouble will not occur with Viodar. The preparation has, in fact, been found valuable in the treatment of skin affections, reasonable watchfulness being exercised. Viodar for internal use has a dosage varying with its strength; the 1 in 1000 preparation, it is suggested after practical trial, should be taken in doses of from one to two teaspoonfuls, a teaspoonful containing approximately gr. 1/20 of iodine virtually in a nascent condition. The equivalent dose of gr. 1/20 is obtained by the administration of 10 minims of the stronger preparation. It seems we have here an iodine compound which should be valuable for both external and internal use, in the latter case the activity of the iodides being represented in a palatable form.

BRITISH DRUG HOUSES, LTD. (Graham-street, City-road, London, N.) will supply doctors with the following three new preparations: Gaster Siccata, Ergodex, and Vitamin A (B.D.H.). GASTER SICCATA is a preparation of desiccated stomach designed for the treatment of pernicious anæmia, the sto of healthy animals being selected for the purpose. It is supplied in aluminium tubes containing 10 g., this being a day's dose, although the actual dosage will be dictated by the condition of the patient and the result of blood counts. It makes a smooth palatable mixture when suspended in milk, and the mixture is practically tasteless, but can be fla if desired.—ERGODEX contains ergotoxine and ergotinine of the official ergot of rye, the activity of batch being tested physiologically and standardised to contain 0·03 per cent. of ergotoxine. The drug administered orally, the dose varying from 10 to minims according to the individual case and the instructions of the medical man.—VITAMIN A (B.D.H.) solution of vitamin A standardised according to known methods, biologically upon rats, and by test (the antimony trichloride test) devised in the B.D.H. laboratories. The preparation is issued in the form of capsules which contain 3 minims of the standardised solution, the dose being one to t capsules daily. The capsules are issued in tins of 5

LACQUIN (Cow and Gate, Ltd., Guildford).—T firm has placed on the market a preparation of full cream milk to which quinine has been added, making a food tonic of particular application in places where malaria is prevalent. The quinine is provided in a concentrated and digestible form, one teaspoonful of Lacquin containing grs. 2½ of quinine. The manufacturers have evidence that the preparation has a slightly laxative effect and is very easy of digestion.

MILK EPIDEMICS.

X.Y.Z.—We saw the suggestion in a contemporary that, in the majority of milk epidemics, the trouble originates from the premises of a producer who prides himself on the precautions taken to ensure a clean raw milk. Those who are called on to investigate these epidemics usually find it very difficult to say how the milk has become infected, and there are few dairy farmers who do not pride themselves on the precautions they take. All milk epidemics, suspected or proved, are reported to the Ministry of Health which alone is in a position to sift the evidence. The claim of a dairy farmer to have taken adequate precautions will hardly count for much if he does not produce graded milk. It would be instructive to know how many milk-borne epidemics have occurred on dairy farms which supply graded milk since the Milk Designations Order came into operation.

PHYSICIAN.—There has been compiled such a list, but it was an imperfect one. As there can be no common opinion of what the word "qualified" means in this connexion, every list would be open to criticism. Will "Physician," who has omitted to give his or her name, state what proof of qualification is desired for purposes of discrimination?

ADDRESSES AND ORIGINAL ARTICLES

ORTHODOXY AND HETERODOXY IN SURGERY.*

By W. Heneage Ogilvie, M.D., M.Ch. Oxf., F.R.C.S. Eng.,

ASSISTANT SURGEON TO GUY'S HOSPITAL AND TO THE HAMPSTEAD GENERAL HOSPITAL.

It is an ancient and fundamental problem of all institutions to combine security with progress, tradition with discovery. Security without progress is stagnation and decay; progress without security leads to anarchy and ruin.

Orthodoxy is defined as the holding of right, or accepted, views. The word is applied to religion, morals, architecture, the arts, car design—in fact, to any matter of public interest; the private concerns of an individual can hardly be orthodox. In matters affecting the many, a generally accepted standard of orthodoxy is necessary, from which standard any departures are judged. Such departures are termed heterodox; they are continually being made in all directions, and those which stand the test of time, in time become orthodox.

Orthodoxy implies a certain degree of doubt—the possibility of another opinion. In this way it resembles truth. A statement which is axiomatic is not orthodox; it is rarely said to be true, but, rather, accurate. A street plan, an anatomical description, a sum in arithmetic, are accurate rather than true, true rather than orthodox. Orthodoxy and truth are both matters of belief, and what is true and what is orthodox is the belief of the great majority. But to say that a thing is orthodox expresses no view as to the value of a contrary tenet; to say that it is true implies that any other opinion is, in the view of the speaker, untenable.

Tradition is, or should be, the accumulated wisdom of the past—wisdom rather than knowledge, because it includes elements not to be learned from books, but from the experience of life, and, therefore, not to be conveyed by books, but only by experience. True education is *arranged* experience; we do not say to our students: "Take a limb and see what you can find in it," but, "Reflect these structures in this order and you will, or should, find such and such vessels, nerves, or muscles."

Orthodoxy represents chiefly the wisdom and learning of the past and it provides the security of that wisdom. An orthodox moralist, scientist, or surgeon can be trusted to have as much learning as the last generation of his craft. This may seem a small commendation, but in real life, and especially in medicine and morals, it is, in fact, a great one, because over much the greater part of the globe there is no assurance to the public that a physician or a moralist has any learning at all. A man may set up as a preacher or a doctor of medicine without knowing as much of either art as an African witch-doctor.

This, then, is the value of orthodoxy and the machinery of examinations, degrees, and associations which upholds it. This machinery makes certain that a doctor of divinity or of medicine does at least know something of his job. In practice, the public has no other assurance than the label provided by the degree—a degree granted by a committee of the orthodox for a knowledge of orthodox practice. I am not using the word orthodox in any derogatory sense, but as an exact description of the truth, because orthodoxy means, in this connexion, all that which is approved by the committee of experts responsible for the standards; what is heterodox this year may be orthodox next.

There is a much greater need for orthodoxy in surgery than in politics or religion, for the subjects of State or church share with others disabilities or dangers not usually very immediate, whereas a sick man bears an anxiety and responsibility and incurs a danger which is not shared and cannot be put off. He has his back to the wall.

Put yourselves in the place of such a man and suppose that there is no established doctrine of medicine or orthodoxy. One friend tells him to go to so-and-so, another to someone else, and he has no better reason than opinion to choose one rather than the other; nothing better than opinion, because nothing better exists. To him and his friends surgery and medicine are mysteries deeper than Hebrew or English law. It would take him years to acquire sufficient knowledge to judge in his own case; and notice, also, that (always supposing there is no orthodoxy, no established machinery of tests, education, degrees) such a man would not even know where to go in order to give himself the necessary education. He must risk being swindled by teachers almost as ignorant as himself, or by prejudiced pedants a century behind the times.

Everyone knows that this was actually the case of the sick man in surgery not so many years ago, and that it still is the case in a great part of the world. It is because of the misery and confusion caused by the absence of any orthodox standards that they were set up and maintained, and are nowadays defended.

True, they are not so much valued to-day by the laity, because they have no experience of the suffering produced by their absence, but they are strongly maintained and defended by surgeons and physicians, who are well aware, by experience as well as the history of their art, of their value to the whole community. Every medical man has, at some time or other, to patch the sorry work of some quack, if it can be patched; and a very little imagination can tell him what was the state of the sick before surgeons and physicians were obliged to learn something about their profession. In fact, this experience is apt to make him too much the supporter of orthodoxy, too much the enemy of new suggestions, especially from outside the fold.

The Heterodox on Trial.

This leads us directly to the centre of the problem: how to devise machinery for testing the heterodox and for admitting the valuable parts of it into the body of the orthodox. Failure to solve this problem—which is as old as society itself—has destroyed countless kingdoms, churches, and orders. If no machinery exists, as in the case of the old French monarchy, there follows a decay, and the disaster called "revolution," which destroys the good of sound tradition with the bad of self-satisfaction. If too much machinery exists, as in the case of the old Roman religion, which coöpted every new god as soon as he was proposed, tradition is swamped and society finds itself without any standards at all.

This problem, which has proved so difficult to statesmen and churchmen, is even more difficult to surgeons, on account of the special nature of their craft. On the continent the system of large professorial clinics, where the word of one man is law over decades, while assistants grow old and fixed in his service, tends to the perpetuation of local tradition and the cramping of true originality as against mere showmanship. In America, on the other hand, the orthodoxy of past generations is often wrongly condemned on insufficient grounds; treatment is largely a matter of fashion, and each innovation is accepted as an advance, till a newer method displaces it.

---

* The substance of an address delivered to the Chichester Clinical Society.

How, then, is the heterodox, the new, to be tested and admitted into the body of the orthodox, the old and tried? In practice, of course, new treatments, new discoveries, are continually tested and admitted by a dozen different routes; but nearly always, be it observed, from orthodox sources—that is to say, doctors, already proved orthodox, having made discoveries in their practice, bring them to the attention of their colleagues and pupils, either by writing about them, or teaching them, and after a general discussion, carried on for some years in the medical press and among medical men, they are either accepted and enter orthodoxy by way of the accepted text-books, or are dropped.

OBJECTIONS TO THE PRESENT SYSTEM OF TESTING.

The objection made against this system as it works is that it does not work well. Critics point out that it is the original system, as old as medicine itself, which goes back (according to one suggestion) to a period before the appearance of man; that it is slow, erratic, uncertain. One discovery, by a stroke of luck, may catch the eye of an authority and be quickly tested, approved, and taught; another may be overlooked for years, or forgotten altogether.

To the first objection—that the system is old and unbusinesslike, or, as one might say, no system at all—the answer is that it exists, like the British Constitution, only on sufferance, and *dum bene gesserit*. If anyone can devise improvements in it, or a better one, it will be instantly suspended by that fact. To the second objection—that it is uncertain—it may be answered that it is nowadays much less so than it used to be, simply because it is much easier for the medical researcher to get his results and suggestions published, and because the profession, as a whole, is much more receptive of new ideas, much more critical, in the true sense of the word, and less dogmatic.

But the real and unanswerable defence is that, in the present circumstances, there is no other imaginable that could fulfil the necessary conditions. Let us recapitulate these circumstances and conditions. The circumstances are a lay world, ignorant of medicine, of scientific method and, to a very large extent, of the weakness of the uninformed human judgment, against which scientific method has devised its mechanical safeguards—that is to say, a vast mass of population ready to be deceived by any specious lie or self-deceiving wonder-worker; and among this immense gullible crowd a comparatively small number of doctors, surgeons, and researchers, working singly or in groups, but divided from each other not only by space and opinion but also by language and great differences of outlook and education.

It might be suggested that surgery, like statecraft, requires an international headquarters, like the League of Nations, or, rather, the Labour Bureau at Geneva; a central office, where all new discoveries would be demonstrated and all records filed. But anyone who understands the complicated nature of our problems will know what such an institute, to be effective, would cost in buildings and staff, with what suspicion and slights it would have to deal, and, also, how easy it would be for it to earn suspicion and deserve contempt. For it would be surrounded by the pitfalls that bureaucracies dig for themselves—dogmatism, red tape, the superiority complex; in fact, those very perils of which dogmatic orthodoxy itself is the begetter. It would become a Royal Academy of Medicine.

But even if we suppose that such an institution could be devised to avoid academism, we have to admit that it does not exist yet, and is not likely to do so for at least as long as the League of Nations is regarded by half the world as a confidence trick.

So that we are obliged, willy-nilly, to continue in the present system, however unsystematic, and, returning to the problem, we find it to be this: how to improve the present system.

EDUCATION AND SCIENTIFIC ADVANCE.

Now, it seems to me that all institutions, all systems, depend chiefly on the men who work them. Give the British Constitution to Italy, Spain, Poland, America, Germany, Greece, Bengal, and you will find in a year or two that it has changed into something so entirely different that the very Speaker would not recognise it. The reason is that Italians, Poles, Greeks, and Hindus have different ideas; their environment, their history—in a word, their education is different.

If we want to know the cause of that dogmatism which assailed Lister with a bitterness and injustice which appear so inexplicable to us, we have to ask: what kind of men were they who called themselves scientific; what kind of education and environment made them what they were? And we see that the environment was one of conservative reaction; the education was empirical and dogmatic. They were told: "Do this! Do that! This is the way to operate for stone; this tumour is inoperable." They were trained as craftsmen, and not as scientific men.

For the mark of the scientific man is an inquiring and independent spirit. He takes nothing for granted; he is ready for the most surprising development, the most bizarre suggestions, and he brings to both—the orthodox that is accepted and the heterodox that has been proposed—the same critical judgment and the exact methods of practical test and trial.

It seems to me, therefore, that the surest and, perhaps, the only means of combining the security of tradition with the life of progress is by the education of every medical student in the true scientific character. Let it be impressed on each from the beginning of his training that the doctor is not only a servant of the public, bound by the oath of Hippocrates, but a scientific man—one of the same profession with Aristotle, Boyle, Darwin, as well as with Arbuthnot and Lister—and that he cannot default in either capacity without injury to the other and danger to the honourable fame of his calling. Let his orthodoxy be that of Newton and Einstein and we need not fear for the progress of medicine.

The Outlook of To-day.

I have dwelt thus far upon the abstract problems of orthodoxy and heterodoxy—problems which are more philosophical than surgical—and must pass on to consider briefly how these conclusions affect our outlook upon the questions that confront us to-day.

A teacher of the last generation asserted, with considerable justification at the time, that the discoveries of the scientist become incorporated only after considerable delay in the practice of the clinician. It is idle to pretend that there is any failure in coördination between research and practice to-day. The wards and the laboratories work hand in hand; physician and biochemist, surgeon and physiologist, radiotherapist and physicist, bring to each other their problems for solution, their discoveries for practical test. Every branch of our art has been brought, within the last few years, to a higher degree of perfection by methods which have sprung from patient quest in research departments; diagnosis has been enriched by cholecystography and intravenous pyelography, prognosis by tests for the estimation of renal, hepatic, and cardiac function; treatment by such remedies as insulin in diabetes and gas gangrene serum in paralytic ileus. Nor is it only from the laboratories that additions to orthodox teaching have been culled; cardiology has been rebuilt upon the work of a general practitioner, while orthopædic surgery has taken manipulative methods from the bone-setter to employ them in its everyday practice.

Medicine has never been more scientific in its training, more catholic in its scope, or more open in its judgment than at the present time. Honest heterodoxy has no difficulty in obtaining a hearing, nor, if it can prove a case, in securing adoption. Rather, I think, are we too easily wooed, too susceptible to the blandishments of the new. The last five years have seen many examples of this mistaken eagerness. Heterodox methods, honest enough and sponsored by men of repute, have been adopted and widely practised, only to be found worthless after an extended trial.

UNWISE ACCEPTANCE OF NEW METHODS.

The operation of lymphaticostomy, exposure and section of the thoracic duct in the neck after ligature of its junction with the subclavian vein with the object of draining away toxins and bacteria from the abdominal cavity, was introduced in 1923 for the treatment of septic peritonitis. The method appeared to hold out the promise of lessening a mortality that had remained undiminished, while that of other acute abdominal emergencies had been reduced tenfold; it was tried and failed, and the very reasoning upon which it was based was proved to be unsound.

A year later appeared the pioneer work of Hunter on the sympathetic innervation of striated muscle, and Royle's now classical papers upon the treatment of spastic paralysis by the operation of ramisectomy. No surgeon who read these remarkable articles doubted that a new weapon in the treatment of one of the most common and crippling diseases of childhood had been placed in our hands, and many adopted and practised the methods with sincere enthusiasm and confident faith. But faith soon wavered; enthusiasm gave way to doubt, and doubt to profound disappointment. The results obtained by orthopædic surgeons in every country except Australia and the outcome of cases operated upon by Royle himself in England and America have been disappointing; to-day the physiological basis itself of the operation stands discredited.

Periarterial sympathectomy was introduced by Jaboulay in 1899 for the treatment of perforating ulcers of the foot, but is more often associated with the name of Leriche, who has advocated it as a cure not only for gangrene but for chronic arthritis and many other conditions affecting the extremities. I may be premature in citing periarterial sympathectomy as another heterodox method which has been avidly accepted by our profession without sufficient scrutiny of its credentials, and has proved unprofitable; but I know no discriminating surgeon who, recovered from his delight at a few apparent successes, has persisted in the method, nor any disinterested investigator of series of cases who supports it. Further, the physiological investigations of Woollard make it clear that there is no logical reason why the operation should succeed.

PROGRESS THROUGH FAILURE.

Yet to Leriche and sympathectomy, and in far greater measure to Royle and the operation of ramisectomy, we owe the opening of a new page in surgical history which is only now being written—the surgery of the sympathetic system. Though valueless in the treatment of spasm in voluntary muscle, ramisectomy, and gangliomectomy which succeeded it, have proved very successful in the treatment of severe Raynaud's disease, and of occasional value in thrombo-angiitis obliterans—the results in this disease depending from the degree of vasomotor spasm in the unoccluded arteries; ganglionectomy has also given good results in Hirschsprung's disease.

Palliative Operations.

Disorders that arise out of the conditions of modern civilised life can only be treated palliatively, since their cause cannot be eradicated except by a return to barbarism, a step some might approve, but few would advocate. No group of diseases has evoked a greater number of suggested remedies or provided a readier opening for heterodox ones; for where successive methods have failed, unschooled enthusiasm is the more prone to grasp at any that are new and credible. I would mention more especially in this connexion the right-sided abdominal failures, intestinal stasis, coloptosis, cæcal distension, and all the troubles in the right iliac fossa for which the appendix is so often blamed without reason and removed without benefit. These are maladies of civilisation, maladies of early adult life, and preponderatingly maladies of women. They are the outcome of a failure of one or more of the many factors which combine to keep the large bowel working normally under normal conditions—factors mental, muscular, and dietetic. In their earlier stages, before organic changes have taken place in the colon, before its walls have changed their structure and lost their contractile power and become fixed in some faulty place or posture by adhesions, they can be alleviated and even cured by attention to these factors. Many require more radical treatment; the old mechanism is beyond repair and a new one must be constructed.

These chronic right-sided failures are very real problems, familiar to every practitioner and surgeon. The clinical picture which they present has been described by Lane with an accuracy and completeness that has left nothing to be altered or added by subsequent writers. But the record of their treatment by operation must give cause for profound dissatisfaction to any thinking surgeon. Probably more fortunes have been made and reputations lost in this field than in any other.

OPERATIONS ON THE COLON.

The operations which have been described and practised for the treatment of right-sided colonic failures are many, but they fall, roughly, into two categories—those of fixation and those of excision. Both are attractive, for they appear to get to the root of the trouble, and operations of each type have been widely accepted and even incorporated into orthodox teaching; both are equally unsound. The operations for fixation are wrong because they run counter to the general orthopædic principles governing the action of hollow muscular tubes—that they must be free to alter their position and diameter as waves of peristalsis pass along them. The primary fault in this group of diseases is not a failure in fixation, but a failure in propulsive power in the wall of the colon. Wide variations in the attachments of the large bowel, both in the direction of greater peritoneal fixation than the average type and of incomplete fixation, are found in the fœtus and demonstrated by radiography and at laparotomy in individuals who have never had any symptoms attributable to their presence. Failure is due to a deficiency in tone both in the wall of the colon itself and in the postural tone of the abdominal wall which supports the viscera; and while this deficiency may react earlier and to a more marked degree upon those individuals in whom the peritoneal attachments of the bowel are incomplete or abnormal, it will cause trouble sooner or later in all. Where tone is deficient, no artificial methods of fixation will hold the colon against its tendency to prolapse; indeed, by interfering with the wall of the bowel such operations are more likely to hinder still further its propulsive power and convert it into a passive bag dragged down by contents which it cannot expel. The occasional successes of colopexy are due less to the operation itself than to the careful régime and re-education of the abdominal muscles which has succeeded it. Failures are prevalent.

Far more disastrous are the failures of colectomy. For as long as five years after the operation the patients may improve, but after that period they deteriorate steadily, till finally they present the picture of habitual ill-health, a warning to all of us that we cannot scrutinise too jealously the basis of any procedure that is presented to us before we finally admit it to orthodoxy. Complete colectomy is dead; in its time it has probably done more harm than any experiment in the history of surgery. Hemicolectomy remains, but it is only slightly less disastrous. In so far as these operations remove a damaged and useless structure, they are well-founded, but in so far as they destroy the normal mechanism of digestion, they are unscientific. Intestinal digestion is controlled by the ileocæcal sphincter in a precisely similar manner to that in which gastric digestion is controlled by the pylorus. The sphincter remains closed till intestinal digestion is complete, the while movements of segmentation mix up the chyme, and absorption of digestible matter continues. After some few hours the sphincter relaxes, admitting what remains into the cæcum; this residue contains a minimum of nutritive material. By colectomy this natural mechanism is abolished. The contents of the small intestine, as yet undigested, pour into the remaining colon, and their value is lost to the body; the putrefactive bacteria of the colon enter the ileum where they find abundant material in which to multiply, and where their toxins are readily absorbed, owing to the abundant blood-supply and specialised absorptive function of the mucosa in this region. In the loss of the ileocæcal valve can be found the explanation of the ill-results of colectomy.

Removal of an unhealthy colon is justifiable in the more severe type of case, but the degenerative changes which have been described are usually most marked in, or limited to, the proximal colon, where the evils of stasis are intensified by the action of gravity. Total colectomy is, therefore, an unnecessary sacrifice of useful tissue, and hemicolectomy is preferable. But the destruction of the mechanism of digestion can be justified on no grounds but the necessity to eradicate a focus of cancer. The symptoms which follow on the operation—anorexia, sleeplessness, anæmia, loss of weight, and nervous instability—all point to a condition of chronic intoxication, which cannot be relieved, nor its further progress arrested. Three of these chronic right-sided failures have come into my hands within the last year; patients in whom all medical measures, carefully ordered and conscientiously executed, had failed to give any relief. In these three patients I have performed a new operation suggested by Dr. A. F. Hurst—hemicolectomy, with transplantation of the ileocæcal sphincter, carrying its nerve- and blood-supply intact, into the transverse colon. The effect of this operation is to leave an alimentary canal in which intestinal and colonic digestions are still segregated by the normal sphincteric mechanism, but in which the damaged colon has been removed, leaving a large intestine healthy, of sufficient length, and aided throughout by gravity. The immediate results in these three cases have been excellent.

Unjustifiable Heterodoxy.

Closely allied to the subject of honest but mistaken heterodoxy is that of stupid heterodoxy—the introduction of new ideas that are merely the resuscitation of former failures, or are based upon wrong or insufficient reasoning. In my reference files I have a folder, the "Chamber of Horrors," in which communications of this nature are kept. One surgeon describes a case in which he performed ileocolostomy, closing both ends of the large intestine, and reports that the colon slowly distended till it occupied the greater part of the abdomen, and the patient finally died; no one who had read the chapter on exclusion in any text-book of operative surgery would have performed this operation, or, having performed it, would have parted with the secret. Another writes of the operative treatment of fractures, illustrating his thesis with radiograms showing all the faults against which Lane cautioned his hearers in 1910. A third publishes a new operation for gastric ulcer, which is none other than the old one of gastro-jejunostomy with entero-anastomosis, which was abandoned at the beginning of the present century because it was followed so frequently by jejunal ulceration, and which stands condemned by the recent experimental work of Mann.

SURGERY OF THE STOMACH.

It is in the subject of gastric operations that callow heterodoxy is most rife, for the stomach will stand almost anything and almost any operation will do good for a time. I would suggest that all those operations that aim at making an anastomosis between the stomach and the duodenum—gastro-duodenostomy, side to side or end to side, pyloroplasty, Finney's operation, duodenectomy, Billroth I gastrectomy, and Schœmaker's gastrectomy—are based upon unsound physiology and are unprofitable in practice.

Two arguments support them—that the new opening is at the site of the pylorus, and that the food leaving the stomach enters that part of the small intestine that is most used to the presence of an acid medium. The first ignores the essential fact that the pylorus is a sphincter acting under nervous control and that, if it be destroyed, no stoma, wherever placed, can assume its functions. Such a stoma is an artificial opening, emptying mechanically, and that stoma will be best which can be made most easily and perfectly in every case and which remains free to move with the movements of the surrounding viscera and the contractions of its component parts. The pyloric end of the stomach and first part of the duodenum are poor surgical material, thick, friable, and vascular; they must be mobilised for approximation, and are pulled from their natural line and under tension after suture; they are not readily controlled by clamps. When an anastomosis is made between them bleeding is troublesome at the time, leakage is not uncommon afterwards, and the finished operation is seldom a really satisfactory craftsman's job.

The second argument is no more than an unsupported statement. The chyme, after leaving the stomach, hurries with great rapidity through the duodenum and upper loops of the jejunum, so that there cannot be any appreciable difference in the reaction of the contents of the first few feet of intestine below the ampulla of Vater. Recent evidence suggests that recurrent ulceration is as common, or more common, after gastro-duodenostomy than after gastro-jejunostomy, and the results less satisfactory. The older operations of posterior gastro-jejunostomy and the Polya type of gastrectomy have a sounder basis, satisfy more nicely the demands of the surgeon-craftsman, and yield results that are as good as any in surgery.

Heterodoxy and Originality.

Since an enlightened medical public is so willing to embrace any new doctrine which is placed before it with the appearance of sincerity, heterodoxy may prove an easy way to notoriety, if not to fame. The reformer and the revolutionary are heterodox. We are, therefore, prone to accept the converse proposition—that heterodox opinions denote the reformer. Those who would acquire an easy reputation for originality need only trade upon this common fallacy, to be certain of a considerable following. Such spurious heterodoxy may be entirely unscientific and frankly dishonest, as cheiropractic, or the Abrams box. It may be of questionable scientific parentage and of doubtful honesty, as is the case with rejuvenation and some of the surgical cures for deafness More often the method is sound enough and honest enough, and only the proprietary relationship of its sponsor is in question. As in the world of industry, the patentee often dies unhonoured while some commercial magnate waxes rich upon the proceeds of his invention, so in science when advances are made the glory and the profit of them goes to him who is first in the market-place. Within the last few years the injection treatment of varicose veins and the renewed public interest in radium have provided such opportunities for the more alert to adopt methods in whose origin they had no part, to write about them in season and out of season, in the medical press and in the *Times*, to rise from overdrafts to affluence, and from comparative obscurity to international reputations.

Heterodoxy is the expression of initiative, ambition, originality, energy; a native orthodoxy the outcome of the reverse qualities. The heterodox mind craves for individual employment, with the chances of fresh fields to conquer, for victory or glorious failure; the orthodox mind seeks safety, a settled future, regular hours, and a certain reward. Therefore, specialisms are founded by the heterodox, but recruited from the orthodox; after the first generation they tend to become mutual admiration cliques, and to lapse into impenetrable standardisation. They decay. The strata of geology are loaded with the remains of extinct specialists who concentrated all their energies on adapting themselves to one particular aspect of their environment; the environment changed and they, being unable to fit themselves to new circumstances, have perished and given way to a stock that meets conditions as they arise.

Specialisation is of the greatest value to surgery, not because each branch studies some small subject with greater intensity, but because each brings a fresh outlook, a new school of surgical thought, which can be applied with benefit to the rest of the art. Plastic surgery has raised the ideal of meticulous care in the handling of tissues; orthopædic surgery stands not so much for the correction of deformity as for a vision dominated by the study of physiology and the respect of function. Such specialisms are born in the vision of some man, or group of men. They rise, like waves upon the ocean, because some driving force raises the matter around it for a time above the surrounding level; like waves, they should agitate the common body while they are moving and be taken back into its substance when the driving force is spent. Every surgeon should study the leaders of plastic surgery and return to his own work kindled with a new vision of technical perfection. The gospel of orthopædics should animate more than the surgery of crippledom. For specialisms that remain apart tend to a dead and static perfection, having the semblance but not the reality of advance, like waves on the sand of the desert.

The Ideal Attitude.

And now I would return to the main subject of my discourse. Fashions change, but truth is eternal, and what has been accepted by successive generations must be founded upon truth. Therefore, the main body of surgical science and thought is orthodox, and heterodoxy concerns rather the form of its expression. To quote Sir Thomas Browne: "There is yet, after all the Decrees of Councils and the niceties of the Schools, many things untouch'd, unimagin'd, wherein the liberty of an honest reason may play and expatiate with security and far without the circle of an Heresie."

Nor need we be ashamed of our orthodoxy, for orthodoxy accepted for purposes of smooth working indicates a stable and reasoned organisation. The good surgeon is orthodox in his teaching and his public utterances; heterodox in his innermost conscience. Text-books must be orthodox; monographs should be heterodox. We should only beware of an orthodoxy that is accepted without thought and without question, for that indicates an extinct faith.

The fetters of orthodoxy are ready to close round all of us, especially if we work at a teaching hospital. We cannot feed the young upon those untried enthusiasms that mean more to us than all the books in our library, for the ideas which we teach them now, however true they may be, however acceptable to future generations, must pass the scrutiny of the most orthodox of mankind—the examiners in surgery. We are happy if we can keep our faith while we serve as priests in the house of Rimmon. Orthodoxy is with us everywhere—at public discussions, at the meetings of our surgical associations, at the annual gatherings at which we congregate. It is only after the tumult and the shouting have died, when the captains and kings of surgery have departed in their expensive cars and some of the younger spirits gather round cocktails, that men really speak their mind on surgical topics. Here lies the great value in the advancement of surgery of the small and intimate clubs, like your clinical society, for it is in the exchange of theories labouring for expression, the outpouring of enthusiasms as yet inarticulate to a fellow-enthusiast, that new ideas are born.

A barge making its way up the Thames from London to Oxford does not proceed at a uniform rate. At times it is moving forward; at times it remains stationary in a lock; but while it is in the lock, water is flowing in from the higher streams, till finally a new level is reached and a fresh advance is possible. Thus, by alternate pause and progression, it finally mounts to the highest levels. So the advance of knowledge must be wayward: the locks are periods of orthodoxy; the advances, of heterodoxy.

For guidance we have the advice of St. Paul: to prove all things and hold fast that which is good. And the spirit of this counsel should pervade our attitude to surgery; the spirit, and not the letter, for if we try all things, we will do a great deal of harm to our patients in finding that which is good. Ingenuity, courage, and unconventionality are admirable qualities in a surgeon so long as they are not practised on others. Therefore, before we try any new idea, we must first ask ourselves: "Is it reasonable? Has it a scientific basis? Is it safe enough to try on a patient, or should I first try it on myself, or in the laboratory? Has it, or anything similar, been done before, from which I can judge the chances of success or failure? If it has failed in the past, was failure due to a fault inherent in the method, or because some factor making for safety or success was unknown to the man who carried it out?"

If the answers satisfy us, we may proceed to practical tests: if these tests confirm our faith, we must still convince our fellows. We shall have our reward if we have been able, even in small measure, to add to the heritage of orthodox surgery.

THE TREATMENT OF FUNCTIONAL ANOREXIA.

By R. S. Allison, M.D. Belf., M.R.C.P. Lond.,
ASSISTANT PHYSICIAN TO THE ROYAL VICTORIA HOSPITAL, BELFAST; LATE ASSISTANT PHYSICIAN, RUTHIN CASTLE;
AND
R. Picton Davies, M.B., B.S. Lond.,
RESIDENT ASSISTANT PHYSICIAN, RUTHIN CASTLE.

Loss of appetite is a symptom commonly met with in ill-health. Thus there is, to quote examples, generally a distaste for food in the acute stages of a febrile illness, at an early stage in cancer of the stomach, also in chronic renal disease, alcoholism, and advanced tuberculosis. Anorexia is, however, not always a symptom of organic disease. It may occur as a primary and often the sole complaint in persons who are simply "run-down" in health or in others who are passing through acute anxiety or mental or physical strain. Lauder Brunton[1] noted the bad effect which financial worry has on the digestion and appetite of business men, and in these days of industrial depression such influences require no stressing. In young women, again, a disappointment or an emotional shock is often the starting-point of a failure of appetite. Those engaged continually in the preparation of food for others and leading an indoor life are also apt to lose their appetite and suffer accordingly. To the type of anorexia which is not necessarily associated with organic disease the term "functional" may be applied.

Functional anorexia is usually mild and temporary, but in the more persistent forms it may be overlooked by relatives and friends alike until the signs of obvious undernutrition appear. This is because the patient may not complain, and is either unaware of the failure of appetite or seeks to hide it. If unrecognised, it may progress to the condition known as "anorexia nervosa," a name first applied by Sir William Gull[2] to describe three cases in young women who showed distaste for food, profound emaciation, and cessation of the menses. This happily rare complaint, which was also early recognised by Lasègue, has since been described by many writers, notably Dejerine and Gauckler,[3] Sollier,[4] Nathan,[5] Lyon,[6] and Venables.[7] Though it is amenable to treatment, a fatal issue is not unknown, and Elliott[8] has reported the results of autopsy in two cases in each of whom the body-weight at death was under 4 st. The findings showed that death had resulted from starvation, the tissues being denuded of fat.

To whatever cause it may be due, it is evident that persistent loss of appetite will lead in time to undernutrition. The energy needed, not being sufficiently supplied by the diet, is supplemented by the gradual using up of the bodily reserves of fat, glycogen, and protein. In a well-nourished fasting subject 87 per cent. of the total energy is derived from the breaking-down of stored fat and only 13 per cent. from the tissue protein (Lusk[9]). Later, when the fat reserves have been exhausted, protein metabolism is increased. Though total abstinence from food cannot be borne for long, partial starvation can be endured for an almost indefinite period, the duration depending on the initial weight of the patient, the daily expenditure of energy, and the character of the food eaten. Many writers have commented on the extraordinary energy displayed by the subjects of functional anorexia. Clifford Allbutt[10] drew a vivid picture of a young woman "whose daily food might lie on a half-crown piece," who was "busy with mothers' meetings and with what you please else of unselfish effort, yet on what funds God only knows." This feature may be related to the findings of Hassin[11] who studied the effects of famine on Russian peasants. He was struck by the absence of structural changes in the nervous system, even in the presence of extreme emaciation.

Material for Consideration.

This paper is based on the experience gained from 20 cases of functional anorexia treated in the past five years at Ruthin Castle. In all, organic disease has been excluded by preliminary physical examination and testing of the blood, urine, and fæces. In many cases, where the possibility of an obscure underlying physical disease could not be excluded, further investigations were made, such as fractional gastric analysis, X ray examination of the alimentary tract, and estimation of the basal metabolic rate and sugar tolerance.

In Table I. the results of physical examination are summarised. Seven cases (Nos. 4, 9, 10, 11, 15, 17, 20), belonged to the anorexia nervosa type and showed almost complete loss of appetite, emaciation, and amenorrhœa. The lowest weight in the series was 4 st. 6 lb. in a subject (Case No. 17) whose height was 5 ft. 3 in. The average weight for a woman of her age and height would be 9 st. In the more severely undernourished cases the skin was dry and parchment-like, and subject to bruises on prominent parts and patches of eczema. The extremities were cold and blue and the temperature was generally subnormal with a slow pulse. The systolic blood pressure was below 100 in five cases, below 120 in 12, and in none was it above 140 mm. This lowering of blood pressure is in accordance with the findings of Cathcart[12] and Rostoski,[13] who noted a similar fall in starving subjects. Inquiry into the questions of sex, age, and civil state showed a preponderance in females (19–20), and in single persons (16–20), and the average age for the series was found to be 33.

TABLE I.

Case	Sex and age.	Civil state.	Height.		Weight.		Menses	B.P.	Pulse-rate.	Temp.
			Ft.	*In.*	*st.*	*lb.*				
1	F. 36	S.	—		8	2	N.	90/60	68	98·4°
2	F. 32	S.	5	10¾	7	9	Irreg.	104/76	72	97·6°

13	F. 29	S.	—		8	0	N.	115/90	66	98·0°
14	F. 53	S.	—		5	10	N.	140/70	98	98·2°
15	F. 29	S.	5	5	7	2	Am.	70/50	70	97·6°
16	M. 20	S.	5	10	10	9	—	125/80	76	97·8°
17	F. 25	S.	5	3	4	6½	Am.	92/66	60	98·4°
18	F. 39	M.	5	6	8	11	N.	136/92	68	97·0°
19	F. 39	S.	5	4	6	8	N.	118/80	72	98·2°
20	F. 23	S.	5	7¾	6	2½	Am.	125/75	60	97·2°

Am. = amenorrhœa.

Notes.—Case 2.—Masculine build. 3. Emaciated; energetic. 4. Emaciated. 6. Cold extremities. 8. Eczema of face. 9. Emaciated; bruising on legs. 10. Emaciated. 11. Cold extremities. 17. Very emaciated; energetic. 20. Emaciated; dry irritable skin.

Preliminary Observations.

Mild and temporary forms of functional anorexia respond readily, as a rule, to simple methods of treatment. A short holiday and freedom from domestic duties is often all that is required to restore the jaded appetite of a tired housewife. A bitter tonic before meals and daily outdoor exercises are required for others. The 20 cases which have been selected in this instance had not, however, responded to home methods and had been referred for hospital treatment. When there is persistent anorexia with loss of flesh it is generally advisable to separate the patient from home and relatives. Once away from the influence of over-anxious parents and the home atmosphere a patient may do well if put on an ordinary full diet, and in many of the cases treated no other steps were necessary. In other cases the loss of appetite persists even after removal to hospital, and in these more specific methods are required.

In many cases inquiry will elicit a history of a shock, anxiety, or disappointment which preceded the loss of appetite. Whenever possible difficulties should be adjusted, but only too frequently the circumstances are such as may not be readily altered. Often, too, the anxiety or shock is in the past, and the patients have sunk into a state of indifference or carelessness. They are probably suffering from the effects of prolonged semi-starvation as much as anything. Improvement in nutrition and the passage of time will therefore play an important part in restoring the lost balance. Though, in this paper, the physical aspect of the problem is considered more in detail, it is not intended to ignore the all-important and—in anorexia nervosa—ever-present psychological aspect. Psychotherapy will play an important part in treatment and success will depend largely on the degree to which the patient will coöperate with the doctor. The confidence of the patient must be secured in the early days and care must be taken to do nothing subsequently which would alienate goodwill. Detailed psycho-analysis has been given a careful trial, but is not, in our experience, needed or advisable.

A few days should be spent before active treatment is commenced in studying the character and extent of the anorexia. A patient may state that she cannot eat large quantities of food. When, however, the amount is reduced the same tendency to leave a part uneaten persists, and of average-sized meals from half to two-thirds, as a rule, is left uneaten. There is frequently a dislike for certain types of food, such as eggs, milk, potatoes, or puddings, and a fondness for others, usually of much lower nutritive value, such as fruit, salads, tea, and coffee. In cases of persistent anorexia with steady loss of flesh it is an advantage to know how much food is actually eaten when the patient is left to her own devices. For three consecutive days, therefore, a note is kept of the quantities given at the various meals and the amount left untouched after the meals. The caloric value of the food eaten can then be calculated. In Case No. 20 the weight on admission was 6 st. 2½ lb. and the height 5 ft. 7¾ in. The average weight for a woman of this height would have been 9 st. 8 lb. This patient was therefore 47½ lb. under weight. Loss of appetite had followed a period of overwork for an examination and weight was being lost at the rate of about 1 lb. a week. The diet was measured for three days. Had all the food been eaten the value of the diet would have been 1900 calories, but as almost half was left uneaten the value of what was ingested was about 1000 calories. On this meagre diet the patient was doing a full day's work, with inevitable loss of flesh.

Dietetic Treatment.

In considering this an analogy may be drawn with the treatment of obesity resulting from excessive appetite. It is, of course, no more necessary to fast a person in order to lose flesh than it is to overfeed another to gain it. The obese subject must have the diet reduced and take more physical exercise. The undernourished subject must increase the amount of food eaten and reduce the expenditure of energy. If this is reduced to a minimum very little increase in the diet may be required. Prolonged fasting in the obese often produces ill-effects and, similarly, if undernourished subjects are grossly overfed a violent reaction may occur, with indigestion, loss of confidence, and further depletion of weight. In treating obesity the diet may be made as bulky as possible by the use of soups, vegetables, &c., which, whilst appeasing hunger, have a negligible food value. Conversely, in functional anorexia it is permissible to make the diet as small as is compatible with the necessary requirements. The object of treatment is twofold: to improve the nutrition of the patient in the hope that this may result in a more healthy state of the appetite, and to stimulate the lost appetite by various methods.

IMPROVEMENT IN NUTRITION.

Reduction of expenditure of energy.—The patient should be kept in bed at first in a warm room with a temperature of about 60° F. When patients are in bed, sitting up for meals and reading, the arms and shoulders are often exposed. These should be covered by a warm jacket or cardigan, with long sleeves extending to the wrists, to minimise loss of heat. Part of the afternoon should be spent completely at rest, the patient lying down and sleeping if possible.

Difficulty may be met at first with the more energetic patients in achieving these ends, but as a rule they quickly settle down. Getting up may be allowed later, and the time for this will depend on the results. Indeed, the prospect of it is often a valuable incentive towards eating the required increased amount of food.

Increased diet.—According to the formula of Du Bois the basal requirements can be calculated from W. 0·425 × H. 0·725 × 71·84 (W = weight in kg.; H. = height in cm.). In giving the surface area in square metres by a reference to the tables worked out by Du Bois and Gephart,[14] calories per square metre per hour can be obtained; 25 calories per kg. in 24 hours should be supplied for an average patient. In the Case (No. 20) mentioned above, the weight was 6 st. 2½ lb., or approximately 42 kg. The amount of food required to maintain basal equilibrium was therefore about 42 × 24 = 1000 calories. Actually the patient was eating slightly less than this and doing a full day's work. In such a case the diet should be led on to 1500–2000 calories while the patient is resting in bed.

In arranging a suitable diet for a patient suffering from functional anorexia all appearance of bulk should be avoided, the food being rather in concentrated form and as appetising as possible. Some foods, such as roast pork, salmon, and sausage, though highly nutritious, often prove indigestible, and when this is so should be avoided. The relative values of an ounce of each of some of the common foodstuffs is given below for comparison. The figures given are those in use at Ruthin Castle, many being from food analyses made by Mr. A. J. Leigh, B.Sc.

	Calories.		Calories.
Dripping, suet ..	270	Roast beef or mutton ..	87
Olive oil	248	Egg, boiled	80
Butter	227	Cream	77
Nuts—brazil, almonds, walnuts ..	208–212	Cooked chicken or duck .	68
Grilled bacon	155	Boiled potato	28
Cheese (Cheddar) ..	117	Milk pudding—rice, sago	27
Bread, toasted	93	Boiled sole, cod	26
		Milk	19

The foods which are largely composed of fat (bacon, cheese, lard, butter, nuts, olive oil, and cream) have the highest value, since a gramme of fat yields 9 calories of heat as compared to the 4 calories yielded by a gramme of protein or carbohydrate. Tea and coffee have no food value; soups, salads, vegetables, and fruit a low one. The worth of these in a diet can, however, be increased by the indirect use of fat-containing foods. Thus cream may be advised in preference to milk in tea or coffee. Soup is also improved in flavour by the addition of cream. Cream and sugar are usually taken with stewed fruit, and vegetables are rendered more appetising by the use of butter in cooking. Most people prefer toast to bread, and this is an advantage because, weight for weight, having less water, toast contains more nourishment. Boiled potatoes may be improved by mashing and mixing with cream and butter. The resulting "potato cream" has a high caloric value.

Below is given a sample diet of about 1500 calories made up largely on the above lines. In arranging a suitable diet for an undernourished subject with a poor appetite, it is not necessary to weigh the quantities unless the case is a severe one and there is doubt whether enough food is being taken. As a rule, in the milder cases the necessary amounts of food can be gauged roughly by experience alone.

Solid food is, as a rule, more difficult to take than liquid, and when there is difficulty in increasing the diet it may be supplemented by certain nourishing and yet palatable drinks. In the treatment of our cases these have played an important part, and there are three which deserve mention.

1. *Marlin's mixture* is prepared by mixing equal parts of cornflour, milk, and lactose and stirring; 8 oz. of this mixture has a food value of about 500 cals. The drink is best given in two equal portions some time in the forenoon and at bedtime.

2. *Orange-juice.*—This is prepared from the fresh juice of oranges mixed with an equal quantity of water to which glucose is added. A pint of this will take 150 g. of glucose and the juice of six oranges; the value is about 800 cals. The jug is left by the bedside and the juice may be drunk with meals or at intervals during the day or night. It has an agreeable clean flavour and is readily taken.

3. *Barley-water.*—This consists of barley-water to which glucose and a little lemon-juice have been added. When flavoured with lemon 30 g. of glucose can be contained in one pint and the value is about 120 cals.

DIET OF ABOUT 1500 CALORIES.

		Oz.
Breakfast.		
Two slices of toast; one pat of butter; egg scrambled with butter. Tea with cream, sugar.	Toast	=1
	Butter	= ½
Lunch or Dinner.		
Roast beef or mutton; cabbage cooked with butter; a small milk pudding made with an egg; one slice of toast, butter.	Toast	= ½
	Butter	= ½
	Beef	=1
	Cabbage	=2
	Rice	=1
	Egg	=1
	Milk	=6
Tea.		
Tea with cream, sugar, three slices of bread and two pats of butter.	Cream	=1
	Bread	=1½
	Butter	= ½
Dinner or Supper.		
Tomato soup (about 6 oz.) to which cream is added. Fish, potato, cream, stewed fruit with cream and sugar. One slice of toast with a pat of butter and a little cheese.	Cream	=3
	Fish	=1
	Potato	=2
	Butter	= ½
	Fruit	=3
	Toast	= ½
	Cheese	= ½

After a start has been made with the diet such as has been described, of about 1500 calories, the addition of one of the above will bring the value up to about 2000 calories, which is more than ample for a person lying in bed. Attempts may then be made to increase gradually the amounts of solid food taken. As far as possible the increase should be almost imperceptible. The patient is weighed weekly but no comment is made except that progress is favourable. It is undesirable that a patient should be aware one week that she has not gained weight and equally undesirable that she should think that with the gain of 1 or 2 lb. efforts may be relaxed. In a severely undernourished person who is practically refusing food it may be necessary to insist on the food being eaten by being present at meal-time. This was only required in a few cases.

IMPROVEMENT IN APPETITE.

This usually occurs gradually as weight is gained, but its return may be encouraged in the early stages by a variety of measures.

Bitter tonics and acid.—The drugs most frequently used to promote appetite are the bitter tonics and particularly gentian and strychnine with dilute hydrochloric acid. The prescription which was most used in our cases was tinct. nucis vomicæ ♏ 5, ac. hydrochlor. dil. ♏ 10, glycerini ♏ 30, inf. gent. co. ad. 1 oz. An ounce of this was given before meals thrice daily. It is rational to suppose that those cases which show subacidity of the gastric juice are most suitable for treatment with acid; seven of the 20 cases had subacidity when examined with a fractional test-meal. Boas,[15] writing on the value of bitters in the treatment of anorexia, states that they are not of much value in prolonged cases but do good in cases where there is temporary failure of appetite. This is in accordance with our own experience, and we have found them more useful in the milder types and in the more severe cases after a start has been made.

Insulin.—Since its introduction in the treatment of diabetes insulin has also been used to promote appetite. Many writers have reported their experience of it in the treatment of anorexia. Among these may be mentioned Vogt,[16] Falta,[17] Appel, Farr, and Marshall,[18] Levi,[19] Short,[20] Moutier,[21] and Frank. Vogt and Falta noted that it improved the general as well as the carbohydrate metabolism. Appel and Farr treated 33 undernourished psychotic patients who were complaining of loss of appetite. Of these 16 were males, and the average gain per week was 3 lb. Thirteen were females, and with dieting alone they gained about a pound a week. With insulin in addition they gained an average of 2½ lb. a week. These authors stressed the necessity for careful supervision, as three of their patients developed severe hypoglycæmia. The dose they used was from 10–40 units daily. Short reported seven cases of loss of appetite successfully treated, but noted that the effects of insulin in improving the appetite wore off after a time. He advised ten units half an hour before meals. Moutier obtained good results with insulin in nine of 23 cases. He began with five units twice a day and increased the dose to 20–30 units.

In many of the present series of cases sugar-tolerance tests were performed during the preliminary investigation; 60 g. of cane-sugar were given on a fasting stomach, first thing in the morning, the patient resting in bed and the blood-sugar being estimated at half-hourly intervals by Hagedorn's method. The blood-sugars were within the normal range in all the cases, but in some tolerance appeared to be slightly decreased (Cases 10, 11, 13), whilst in others (Cases 8, 20) it was slightly increased. In these two cases with a low range of blood-sugar it appeared likely that insulin might be dangerous. The figures are given as follows:—

Case	Resting	Blood-sugar: Hours.					Result.
		½	1	1½	2	2½	
1	1·10	0·10	0·16	0·12	0·11	0·11	Normal.
2	0·08	0·11	0·13	0·15	0·08	0·07	„
8	0·07	0·11	0·10	0·10	0·10	0·08	Increased.
10	0·11	0·15	0·20	0·16	0·11	—	Decreased.
11	0·09	0·16	0·20	0·21	0·18	0·12	„
13	0·09	0·17	0·15	0·20	0·14	0·14	„

Insulin was used to promote appetite in six cases. The results obtained were not striking. In some there was no appreciable result; in others a sense of weakness or emptiness followed the injections. In none was a pleasant sense of appetite produced. The doses given were small, from 3–10 units twice daily, the usual being five units. It is possible that better results might have been achieved with larger doses, but the experience in one case (No. 9) was sufficiently alarming to discourage higher dosage.

This patient was suffering from anorexia nervosa and weighed 5 st. 3 lb. She had been having insulin in doses of five units before breakfast and five units before dinner. After a week she was found one afternoon in a state of hypoglycæmia with symptoms of severe collapse, feeble pulse, cold extremities, and extreme mental apathy. Glucose by mouth and per rectum and a subcutaneous injection of adrenalin ♏ 5 relieved the symptoms.

The best results were obtained in patients who were not severely undernourished and who were already improving with diet alone. After three or four weeks the appetite often showed a tendency to flag, and it was then that insulin appeared helpful, in small doses given for a short period such as a week or a fortnight. After that its effect appeared to wear off.

Thyroid.—Thyroid has been used as a means of promoting appetite. Lévé gave small doses of the extract by the mouth to women suffering from functional anorexia and observed that the appetite returned and the weight increased. In starvation there is a lowering of the basal metabolism, and Benedict,[22] experimenting with students on a reduced diet, noted an average fall of from 101 to 88·5 per cent. in six weeks. The conditions in functional anorexia are akin to those of semi-starvation, and Moeller[23] found in four cases of this kind a fall in proportion to the degree of under-nutrition. Estimations of the basal metabolic rate were made in nine cases. In only two, however, was the result below 90 per cent. Both of these (Nos. 9 and 15) were much undernourished and suffering from anorexia nervosa. In emaciated subjects with an intense anorexia it is probably undesirable to increase metabolism artificially unless one can be sure that an adequate quantity of food will be eaten. With a persistent anorexia such a procedure would only hasten the loss of flesh. The extract may be tried, however, with safety in half-grain doses twice a day at first in patients of the milder sort with a slow pulse and lower basal metabolic rate who can be persuaded to eat.

Gastric lavage.—Gastric lavage is of value in the treatment of chronic gastritis resulting from alcoholism, renal disease, or benign pyloric stenosis. Improvement in appetite and gain in weight result. Tixier[24] has found it helpful in the anorexia of infants and young children. In the functional anorexia of adults there is often a complaint of fullness after meals. In seven cases of this series (Nos 2, 4, 9, 12, 13, 14, 20) the stomach was found to be dropped and relaxed, whilst a seven-hour gastric residue was present in one case (No. 13). Though it is unpleasant at first, patients rapidly accustom themselves to gastric lavage and learn to do it themselves. The best time is about 6 P.M. The residues of the day's food are then washed out with a warm solution of bicarbonate of soda, about a teaspoonful to the pint, and the stomach is left empty to receive the evening meal. During the night the stomach has again a chance to empty, so that emptying occurs at least twice in the 24 hours. In three cases in which this method was employed, improvement in appetite resulted, and one case (No. 20) gained 26 lb. over a period of several months during which the treatment was carried out by the patient herself. Lavage may be given daily at first and after a time thrice a week; later it is reserved for occasional use as required.

Periodic Fasts.—The practice of fasting dates back to the earliest times. The first symptom which fasting produces is hunger. In experiments with rats, Pembrey and Spriggs[25] noted that when an animal was fed after a fast there was a rapid increase of weight, the previous hunger apparently acting as a stimulus to the assimilation of food. These observations confirmed those of earlier workers, such as Seeland, Barfurth, and Noé.[26] Though fasting has been used as a therapeutic measure in many diseases, we have not met with references to its possible value in the treatment of loss of appetite. In the past year six cases have been treated by this method on Dr. E. I. Spriggs's suggestion. The impression gained is that it is a valuable means of promoting appetite and gain of weight. It is applicable to all grades, from the mild variety to the more severe type of anorexia nervosa. Moreover, patients who are struggling with their appetites enjoy a periodic rest, and are more willing to eat the prescribed amounts of food on the following days.

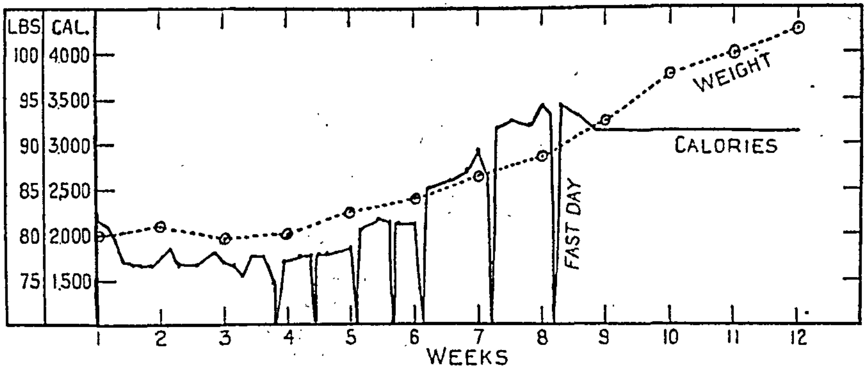

Chart showing a gain of 23 lb. in weight under treatment by rest in bed, dieting, and periodic fasts.

Treatment is begun with a "fast" day. No solid food is taken but water may be drunk, and half a pint of orange juice, prepared in the manner described above (400 calories), is left by the bedside. On the next three days a diet of about 2000 calories is given. On the fifth day there is another fast, and so on with three days' full diet and one day's fast. Thus in a week there are two fast days at first. As appetite improves, only one fast day is given a week, and later fasting is reserved for occasional use only. The patient is, of course, kept in bed on fast days as well as on other days at first, but later getting up may be allowed on the full diet days. An example is given below to show the benefit which may result from periodic fasting.

The patient, a woman (Case 14), weighed 5 st. 10 lb. and complained of loss of appetite and tiredness. She was persuaded with difficulty to eat a light diet which had an average value of about 1500 calories. Resting in bed she gained weight slowly: 4 lb. in just over a month. Fast days were then given. The actual figures are arranged below for comparison over a period of ten consecutive days.

Persuasion. Day.	Caloric value.	*Periodic Fasts.* Day.	Caloric value.
1	1,750	11	Fast (490).
2	1,600	12	2,300
3	1,530	13	2,250
4	1,630	14	2,430
5	1,620	15	1,700*
6	1,630	16	2,410
7	1,530	17	2,830
8	1,680	18	Fast (380).
9	1,040	19	2,850
10	1,570	20	2,420
Total	16,180	Total	20,060

*Half-day fast.

After the first fast the appetite improved and more food was eaten on the succeeding three days. Before it began to flag again another short fast was given. The figures show that even with two whole days' and one half-day's fast more food was eaten than on the previous ten days without fasts. At the end of a month on this régime 9 lb. weight had been gained as compared with the 4 lb. gained in the preceding month without fasts.

Results of Treatment.

In Table II. the results of treatment are set out. It will be seen that, of the 20 cases treated, 16 responded to treatment and did well, recovering their appetite and nutrition. The remaining four cases did not improve. They were treated some time ago and their present state is known. The first (Case 1), a single woman aged 36, had lost her appetite after the death of her mother and an operation on the abdomen. She was profoundly depressed throughout and would have lost weight through lack of food had she been left to herself. As it was, with the most strenuous efforts at persuasion, she held her weight but did not gain, and left in much the same state. After this she was treated in a nursing home and in a hospital for nervous diseases without improvement. Her present state two years later is much the same as then. In this case the mental state of depression dominated the picture. The second case was an energetic married woman of 42 (Case 7). Her energy expenditure was much in excess of the small amount of food she ate and she resented interference with her diet. In every way she appeared to be very well except that she had no appetite, and she also is in much the same position two years later. The third case was similar to the second and occurred in a young married woman of 29. The fourth case (No. 9) has been about 5 st. 3 lb. for years. In both the third and the fourth cases there appeared to be an element of mental deficiency.

Of the 16 cases which did well, success in restoring appetite and nutrition seemed to depend on: (1) the gaining of the patient's confidence; (2) the degree of

P.F. = periodic fasts. G.L. = gastric lavage. Imp. A. and N. = Improved appetite and nutrition.

mental stability; and (3) the coöperation of the parents, so that time was allowed to obtain the necessary result. The optimum period of treatment for a case of severe anorexia or anorexia nervosa appeared to be about three months. In this time 1–2 st. could be gained and appetite recovered in most cases. As a rule the greatest increase of weight was made by the most undernourished patients. Of the different methods used, including dieting, insulin, gastric lavage, and bitter tonics, the best results seemed to follow the practice of periodic fasts and increasing the diet after the fast days. The method has the advantages of being free from risk and acceptable to the patient. The accompanying graph represents the progress made by a patient on this régime, the curves showing the gain in weight and the diet in calories with fast days.

HEART-BLOCK FOLLOWING ACUTE APPENDICITIS.

BY LESLIE COLE, M.D. CAMB., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

THE following case seems worth recording because heart-block is an extremely rare sequela of appendicitis, and because electrocardiographic tracings were obtained at frequent intervals illustrating the rapid sequence of changes which occurred.

Record of the Case.

The patient, a man aged 41, was admitted to Addenbrooke's Hospital on Sept. 4th, 1930.

For five years he had had attacks of pain in the abdomen at infrequent intervals. These had not lasted more than a few days, and he had not taken very much notice of them. In all other respects he had been perfectly healthy. He had never had any symptoms suggestive of acute rheumatism or syphilis, and his family history was good. Two days before admission he had been seized with severe pain in the right iliac fossa, associated with vomiting and constipation, and on admission he was seen by Mr. W. H. Bowen, who diagnosed acute appendicitis.

Operation was performed at once and an acutely inflamed appendix removed without difficulty. There was no sign of gangrene or perforation, but flakes of lymph were present on its peritoneal surface and on the adjacent omentum. After operation progress was uneventful until Sept. 8th. The temperature, which was 101° F. on the day after operation, subsided gradually. The wound appeared quite healthy, and there were no other signs or symptoms during this period.

On Sept. 8th the patient did not feel quite so well, but nothing abnormal was noticed. On the early morning of the 9th the *pulse* became slightly irregular, and appeared to be dropping beats. At 6 A.M. he felt dizzy and complained of abdominal discomfort, but this was ascribed to an aperient which he had been given. On the morning of the 10th the pulse was quite irregular, the rate was slower than it had been (72), and at times several beats appeared to be dropped. The patient on the whole seemed better and was beginning to eat well.

On the 11th, at 3 A.M., the pulse suddenly became very poor and irregular, and the patient became pale and collapsed and perspired freely. He complained that he felt a terrible sinking sensation in his chest and a sense of impending disaster, although there was no actual pain. These sensations gradually passed off and the pulse improved.

I was first asked to see him at 10 P.M. on the same day. He was then still rather pale and collapsed. The pulse was of good volume, and regular but for one or two missed beats in every minute. The rate was 72. The heart did not appear to be enlarged, and the sounds though faint were otherwise normal. There was no evidence of arterial disease in the optic discs or elsewhere. The blood pressure was 110/75. The only other symptoms were a slight pain in the right shoulder which had come on the day before and might easily have resulted from lying in one position, and acute congestion of the vessels of the right side of the conjunctiva, which had also come on the day before. The wound seemed to be perfectly healthy.

At 10 A.M. on the morning of the 12th the condition was unchanged except that the pulse-rate was slower (45), and dropped beats were more frequent. At times the rate would drop to 30 for five or ten consecutive beats. By 4 o'clock in the afternoon the pulse-rate was never above 35, and occasionally it was 24 for periods of a minute or more. From this point the clinical condition of the patient improved steadily, and the pulse-rate gradually quickened. On the morning of the 13th the rate had risen to 70, and no dropped beats could be detected on clinical examination. Apart from the variations in rate no abnormal physical signs were detected in the heart at any time, and by the 15th the patient was feeling quite well, and the blood pressure had risen to 140/90. The first electrocardiogram was taken at 10 A.M. on the 12th, and then once or twice daily until the 17th. The tracing on the 17th was normal but for a P–R interval of 0·28 second, and on the 20th was quite normal.

A teleradiogram taken one month after the onset of the attack showed no enlargement of the heart. The Wassermann reaction was negative.

Treatment.—During the acute phase of the attack and for 14 days afterwards the patient was kept at absolute rest. Morphia was given six-hourly from the 11th to the 13th, and after this gradually stopped. Return to normal activity was graduated, and the patient was allowed to resume work as a signalman ten weeks after the onset of the heart symptoms.

Heart-block in Infections.

Cases of transient heart-block are met with in the course of various infections, but are most frequently associated with acute rheumatism. In this condition they are by no means uncommon. Parkinson, Gunson, and Gosse,[1 2] in an analysis of 50 consecutive cases of acute rheumatism, found a P–R interval greater than 0·2 sec. in 11 cases. Some degree of block persisted for periods of from 1 to 18 days, but had disappeared before discharge from hospital. Four of these cases had dropped beats, and in one a 2 : 1 block was present which lasted for two days. Cohn and Swift[3] made a similar study in 37 cases, and found that the P–R interval was prolonged in eight, with dropped beats in one. Bain and Hamilton[4] in 50 cases found a prolonged P–R interval in two. White[5] described a case in which acute partial heart-block was one of the initial signs of onset of rheumatic fever in a boy of 18. Before any signs of acute rheumatism had appeared the a–c interval was found to be 0·5 sec., and beats were dropped. Four days later, when typical signs of rheumatic fever had appeared, the a–c interval was still prolonged, but six weeks later it had become normal. Other cases of heart-block in acute rheumatism are reported by Butterfield,[6] Naish and Kennedy,[7] Cowan, Fleming, and Kennedy,[8] Cowan, McLeod, and Paterson,[9] Christian,[10] Lewis,[11] Mackenzie,[12] Peabody,[13] Esmein, Pezzi, and Donzelot,[14] and Routier.[15]

Partial heart-block is occasionally met with in diphtheria. Marvin and Buckley[16] have collected nine proved cases from the literature, and added two more to these. In these cases onset was from the third to the twenty-first day of the disease, and was followed by death in all but one case. Post-mortem examinations done in some of these revealed extensive changes in the myocardium, with profound damage to the conducting system. The one case which survived, recorded by Parkinson,[17] developed complete heart-block, which was followed by auricular fibrillation which persisted.

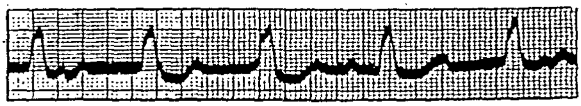

FIG. 1.—10 A.M., 12 × 30. Partial heart-block and intraventricular block. Q R S 0·12 sec. In this and subsequent figures the vertical lines are 1/5 and 1/25 sec., and lead II. alone is shown.

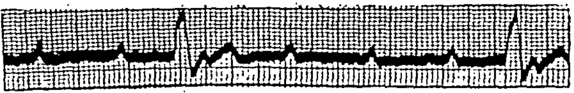

FIG. 2.—4 P.M., 12 × 30. Partial heart-block up to 4 : 1. Q R S 0·12 sec.

More rarely heart-block is met with in other infective conditions. Lewis[18] mentions that it occurs in pyogenic infections, influenza, typhoid, scarlet fever, and pneumonia, and mentions a case of transient partial heart-block from a case of subacute cystitis[19] resulting from an infection by an organism of the coli group, and a case of temporary heart-block in pneumonia. Mackenzie[20 21] mentions cases in influenza, septic poisoning, and puerperal fever; Magnus-Alsleben temporary heart-block in pneumonia[22]; Wenckebach a case in influenza[23]; Jellinek and Cooper[24] a fatal case in a patient with acute gonorrhœal sepsis in which autopsy revealed anæmic necrosis in the region of the bundle of His; James[25] a fatal case during the course of streptococcal septicæmia, in which autopsy revealed an ulcer in the intramuscular septum. Recorded cases with instrumental confirmation of the severer grades of heart-block during the course of infections other than rheumatism are, however, uncommon. Probably some of the attacks of bradycardia noted in such infections are due to transient attacks of heart-block similar to the present one.

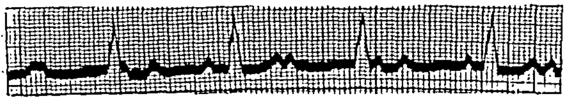

FIG. 3.—10 A.M., 13 × 30. Partial heart-block 3 : 2. Q R S 0·1 sec.

The happy result in this case leaves the cause a matter for speculation.

CAUSE OF THE BLOCK.

There appear to be two ways by which heart-block could have been brought about. The conductivity of the bundle of His may have been lowered by poisons absorbed from the infected appendix. This seems very unlikely, because not only was the main source of infection removed four days before the first sign of heart involvement appeared, but the slight signs of general toxæmia which were present at operation subsided steadily, and there did not appear to be more than slight local inflammation in the vicinity of the wound after operation. Further, any signs and symptoms which were present came on too rapidly and cleared up too quickly to have been associated with any gross general damage to the muscle of the heart, and to explain it in this way such a poison must have had a selective action on the conducting tissue. A more likely explanation is that a mild bacteriæmia was associated with the subsiding local inflammation in the appendix region, and caused a small focal inflammatory lesion in the region of the bundle of His which interfered temporarily with conduction. Possibly the pain in the right shoulder and the inflammation in the right conjunctiva may have been due to similar focal lesions. Such lesions have been described by Cowan,[26] who regards them as incidents in a general pyæmia. The larger lesions are generally found in septic infections and the smaller in cases of pneumonia, small-pox, enteric fever. They may be compared to the focal inflammatory lesions found in the muscle in acute rheumatism which have been described by Aschoff,[27 28] and Coombs.[29 30]

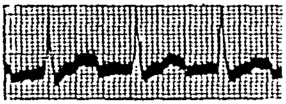

FIG. 4.—10 A.M.; 14 × 30. No dropped beats. P–R 0·32, Q R S 0·08 sec.

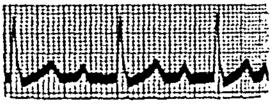

FIG. 5.—15 × 30. P–R 0·23 Q R S 0·08 sec.

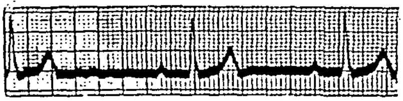

FIG. 6.—17 × 30. P–R 0·28. Q R S 0·06 sec. Slow sinus rhythm.

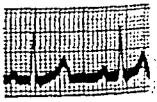

FIG. 7.—26 × 30. P–R 0·16. Q R S 0·06 sec.

The occurrence of such a chain of symptoms after appendicitis is an interesting clue to the way in which an acute infection, other than rheumatism, may lay the foundation of myocardial disease. Had the conducting tissues not been affected in this case, the signs of cardiac involvement would probably have been so slight that they would have escaped notice.

In conclusion, I should like to thank Dr. Ffrangcon Roberts for the radiological examination in this case.

SULPHUR, TURPENTINE, AND ALEPOL INJECTIONS

IN PERSISTENT PSYCHOSIS.

BY DUNCAN MACMILLAN, B.Sc., M.D., D.P.M. EDIN.,
ASSISTANT PHYSICIAN TO THE CRICHTON ROYAL, DUMFRIES;
AND
ANDREW McNAE WYLLIE, B.Sc., M.B. GLASG.,
CLINICAL PATHOLOGIST TO THE HOSPITAL.

IT has been frequently observed in the insane that intercurrent febrile illness may cause striking amelioration of the mental symptoms. Patients have been observed to improve or even recover after acute infections such as erysipelas, typhoid fever, or acute pyogenic disease. The treatment of general paresis by induced malaria is an example of the therapeutic application of this phenomenon. Yet it remains a mystery how this amelioration is effected. It may be that the production of phagocytes and antibodies is stimulated, and some hidden source of chronic bacterial toxæmia is dealt with; or the stimulation of metabolism may increase oxidation and hasten elimination of toxic waste products from the cortex and body generally; or the exposure of the brain cells to a supernormal temperature may exercise some specific influence. Another theory is that the improvement is psychogenic in origin, attributable entirely or partially to the pain or discomfort experienced and the extra attention and nursing involved. These factors will tend to focus the patient's attention upon reality, and compel him to some degree of extraversion.

Three Remedies.

In this investigation three substances known to cause a bodily reaction were selected for trial, and an attempt has been made to assess their therapeutic value in cases of persistent psychosis. The bodily defence mechanism, as evidenced by leucocytosis and the thermal reaction, was observed with the object of discovering whether a relationship exists between those physical phenomena and the mental effect produced. In assessing the value of any new therapeutic agent, it is essential that the patient selected for treatment by the new means should first be given a fair trial with ordinary therapeutic measures. Otherwise, cases which would have recovered with ordinary routine treatment, or spontaneously, would be included in the number of successes claimed for the new treatment. Especially is this true in cases of psychosis, where recovery is often unexpected or spontaneous. Apart from a small number of those treated with turpentine, all the cases have resisted, for at least six months, the usual standard treatment of the mental hospital—rest, open air, dieting, tonics, regulation of habits, and correction of physical disorders.

SULPHUR IN OLIVE OIL.

K. Schroeder[1] claims favourable results in the treatment of dementia præcox by means of Sulfosin, a 1 per cent. solution of sulphur in olive oil.

A series of 21 cases was treated by us with injections of a 1 per cent. solution of sulphur in olive oil. The solution was made by rubbing up the required quantity of the purest flowers of sulphur with pure olive oil in a mortar and placing the suspension in a hot oven until all had dissolved. The resulting sterile solution was put up in ampoules. The injections were given in increasing doses, commencing with 1 c.cm., and increasing each time by 1 c.cm. They were given at approximately five days' intervals. One case was treated entirely with sulfosin Leo (Copenhagen), while four other cases received two injections of sulfosin Leo and three subsequent injections of our own product. The general immediate effects, the pyrexia and the leucocytosis, did not differ whether sulfosin Leo or our own product were used.

The injections were made intramuscularly in the gluteal region, and only a few of the patients complained of pain. After four hours the temperature rose one degree, remained up for two or three hours, and then returned to normal. This initial rise of temperature was accompanied by a little nausea. After a variable period of from 10 to 16—or even 18—hours from the injection the temperature began to rise, usually reached 101° F., and seldom exceeded 103° F. The time during which the patient remained fevered was very variable; sometimes only seven hours, occasionally as long as 20 hours, probably depending on the rate of absorption as well as on the particular patient's reactivity to sulphur. The pyrexia was accompanied by a leucocytosis (about 20,000 white cells per c.mm.). The number of injections varied from three to ten. Generally it was found that the sixth injection (6 c.cm.) produced the greatest reaction, in a few cases producing a hyperpyrexia of 105° F. When the fever was present some nausea was complained of, and when there was hyperpyrexia actual sickness usually occurred. After the injections the leg was a little stiff, but no lasting pain, tenderness, or other disability resulted.

The diagnoses in the cases treated may be summarised as follows: katatonia, 1; schizophrenia 6; post-schizophrenic dementia, 5; melancholia, 5; manic-depressive psychosis, 1; recurrent mania, 1; hypochondriacal neurasthenia, 1; and paraphrenia, 1.

Recovery took place in one case of recurrent melancholia. The patient was a woman, aged 45, whose outstanding symptoms were agitated depression and suicidal tendencies. She was ill for nine months before admission to hospital and for six months afterwards. During this time she had improved a certain amount, but for some months before the treatment her condition had remained unchanged. She recovered after four injections of sulphur.

Seven cases could be regarded as improved. The diagnoses in these cases were: katatonia, 1; katatonic schizophrenia, 1; involutional melancholia, 3; hypochondriacal neurasthenia, 1; and paranoid schizophrenia, 1. In none of these cases, however, was improvement marked, and in five of them it occurred some months after the treatment. In two

of the cases the psychological effect of the injections was obviously a factor in causing the improvement.

The results are disappointing; this form of treatment seems to be of very limited value in the psychoses.

TURPENTINE.

Pascal and Davesne[2] give an account of the treatment of 257 cases by means of turpentine producing sterile abscesses, and claim very encouraging results. They used a mixture of one part of turpentine of Venice and five parts of oil of turpentine, and injected it into the deeper layers of the subcutaneous tissue of the antero-lateral aspect of the thigh.

In this investigation the same technique was followed. Fifteen cases were given turpentine alone and seven other cases received a subsequent course of T.A.B. vaccine intravenously, the vaccine being administered as the temperature reaction due to the turpentine was subsiding. The amount injected varied from 1·5 c.cm. to 2 c.cm., the former dose as a rule being given to females and the latter to males.

The diagnoses in the cases treated may be summarised as follows: schizophrenia, 9; mania, 2; melancholia, 5; manic-depressive psychosis, 1; paraphrenia, 1; general paresis 1; acute confusional insanity, 2; and post-schizophrenic dementia, 1.

In this series the bodily reaction, as evidenced by the local reaction, leucocytic reaction, and degree and extent of pyrexia, could not be correlated with the mental response. It did not necessarily follow that, because the physical reaction was a severe one, there would be a marked improvement in the mental sphere.

Some hours after the injection the patient complained of pain and itching at the site, and in about 12 hours the temperature commenced to rise and a red brawny swelling appeared. Symptoms increased in intensity for three days and the swelling became fluctuant. The average extent of the swelling was six inches by five. In a few cases a much more extensive and diffuse reaction occurred, affecting the whole outer aspect of the thigh. In two-thirds of the cases the abscess underwent spontaneous absorption, while in the remainder incision and drainage were necessary. The pus was a thin brownish hæmorrhagic fluid containing tissue debris, turpentine globules, and leucocytes. The temperature gradually subsided and returned to normal after a period varying from 3 to 13 days. The pus was examined and found to be sterile. In all cases the patient was confined to bed, and the routine treatment of fever carried out during the acute stage. A little lameness was noticed for a few days after, but no permanent disability resulted.

Only in two cases was the treatment entirely devoid of beneficial effect. They were similar cases, suffering from a severe type of melancholia, with restlessness, suicidal impulses, and such agitation that it rendered them inaccessible. In them the effect of the injection seemed to be merely an increase in their load of misery. No ill-effects were observed except in one patient who was given 2·5 c.cm. of turpentine. A marked, though transient, albuminuria was produced. No impairment of kidney function resulted, but this indicates that it is inadvisable to give more than 2 c.cm. of turpentine at one time. A second injection may have a marked beneficial effect after the failure of the first. In no case did we observe the reactivation of the inflammatory process, at the site of the first injection, described by Pascal and Davesne.

The general impression given by the investigation is that the claims put forward by Pascal and Davesne are unduly optimistic, but that in selected cases the production of sterile abscesses by means of the injection of turpentine is quite a potent therapeutic agent in the psychoses. In an acute recoverable benign type of illness the good effect of the turpentine is potent enough to accelerate the natural process, and thereby perchance it may at a critical moment turn the balance in the patient's favour. In the chronic malignant type of psychosis, a good effect is obtained but the course of the psychosis is not essentially altered. For example, one patient suffering from paraphrenia, who was a very resentful, idle, noisy, uncoöperative person, has become quieter, and is now an active willing ward-worker. Her delusional system is unaltered, and she is still noisy and resentful at times. Again, a general paretic, who was quite unmanageable and taxed the resources of the nursing staff to the utmost, became a pleasant, amenable patient. The subsequent course of T.A.B. vaccine was of no additional value.

ALEPOL.

Alepol is a preparation of sodium hydnocarpate used in the treatment of leprosy by Sir Leonard Rogers. A 3 per cent. solution was made, and injections of it were given intramuscularly, commencing with a 1 c.cm. dose. Injections were given twice weekly, increasing the dose by 0·5 c.cm. each time until a dose of 5 c.cm. was reached. Alepol is said to be the active principle of chaulmoogra oil, and it was considered worthy of trial.

Five cases were treated: two of post-schizophrenic dementia, two of hebephrenic schizophrenia, and one of paranoid schizophrenia. Nine injections were given to each patient, and in one case there was slight improvement.

In each case a white count was performed before, during, and after the course of alepol. The general effect was to produce a mild leucocytosis not exceeding 16,000 white cells per c.mm. We are of opinion that no beneficial effect was produced by this treatment.

Discussion.

On reviewing the results as a whole, no correlation can be found between the physical disturbance produced and the mental changes. A marked and constant increase in the white corpuscles is produced by sulphur in oil, a moderate increase by turpentine, and a slight increase by alepol. Despite the fact that sulphur in oil is capable of stimulating a vigorous reaction of the leucocytes, it does not produce a corresponding mental improvement. Examination of the turpentine series shows that the degree of leucocytosis is not proportionate to the mental improvement; and augmentation of the leucocytosis by means of T.A.B. vaccine has absolutely no additional therapeutic value. Thus, stimulation of the defence mechanism of the body as indicated by leucocytosis, is not the essential factor in effecting mental improvement, and the application of the term "leucogenic shock" to turpentine therapy is undesirable.

In sulphur we have an excellent agent for the artificial induction of pyrexia but, as stated above, little beneficial effect accrued from its exhibition. In the turpentine series no relationship was found between the degree and extent of pyrexia on the one hand and the mental improvement on the other. Although T.A.B. vaccine is a powerful agent for production of pyrexia, its administration was a failure from the therapeutic point of view.

---

[2] Traitement des Maladies Mentales par les Chocs.

Increase of nursing attention is not an essential factor, as patients suffering from acute confusional insanity, who are already receiving constant attention, may show a striking response to the injection of turpentine.

In our opinion pain is the most important psychological factor in the improvement, although it cannot be denied that the extra attention and care bestowed on the patient do cause improvement by keeping him more closely in contact with his environment.

CONCLUSIONS.

1. Sulphur in oil is of limited value as a therapeutic agent in cases of persistent psychosis. Alcpol is of no value. Turpentine has a limited value in selected cases.

2. Pyrexia and leucocytosis are not in themselves sufficient to cause mental improvement. Hence it appears that the amelioration of the mental symptoms, which occurs in psychotics who contract intercurrent febrile illness, is due to some other factor or factors. The psychological factor undoubtedly plays a part, but we do not feel that it is the entire explanation. Probably the stimulation of metabolism, by oxidising and eliminating toxic waste products, is an important factor.

We desire to express our thanks to Dr. Easterbrook, physician-superintendent of Crichton Royal, for valuable advice and criticism, and for permission to publish these results.

SCLEROSIS OF THE PULMONARY ARTERY WITH THROMBOSIS.

By O. Brenner, M.D. Birm., M.R.C.P. Lond.,
PHYSICIAN TO OUT-PATIENTS, QUEEN'S HOSPITAL, BIRMINGHAM.

Four main groups of diseases of the pulmonary artery are generally recognised:—

(1) *Congenital* (usually stenosis, but occasionally dilatation of the pulmonary arteries).

(2) "*Primary sclerosis*," where there is no obvious cause. Several different lesions are included under this name. Usually the walls, and especially the intima, of the small branches of the pulmonary artery are thickened and the lumen narrowed, and there is also atheroma of the larger branches. Probably the cases described by Rogers[16] in India should be put in this group, as the evidence of a syphilitic origin would not now be thought sufficient. In Veale and Coombs's[18] case in a child of 5 there were lesions resembling atheroma. Clarke's[5] Cases 3 and 4 showed similar lesions, though the microscopical appearances were rather anomalous. Clarke suggests that, as these lesions are sometimes found in children, the condition is due to an inborn deficiency of the material of which the pulmonary arteries are made.

(3) *Syphilitic disease* which may occur alone or together with other syphilitic lesions such as syphilitic aortitis, or, according to Arrillaga[1] and others, syphilitic bronchitis. There are two main types of lesion: (*a*) syphilitic endarteritis or panarteritis of the small branches, usually associated with atheroma of the main branches, and (*b*) lesions of the main branches closely resembling syphilitic mesaortitis. In such cases aneurysms may occur. Sometimes both types of lesion are combined. Although syphilitic pulmonary artery disease is rare, the literature seems to be concerned chiefly with this type of case.

(4) *Secondary sclerosis*, occurring in cases in which the pulmonary blood pressure is thought to be raised, such as fibrosis of the lungs, emphysema, and mitral stenosis. This is by far the commonest group, but it has attracted very little notice.

CLINICAL PICTURE.

The best known clinical syndrome of pulmonary artery disease is often called Ayerza's disease. The patient is usually middle aged and has suffered from cough and dyspnœa for many years. At this stage he presents the clinical picture of chronic bronchitis with emphysema. After many years the previously slight cyanosis increases until the complexion is almost black (hence the term *cardiacos negros*) and the dyspnœa also increases, though usually not in proportion to the cyanosis. Hæmoptysis is common and, according to Laubry and Thomas,[13] may occur before the development of extreme cyanosis. It is then, in the absence of evidence of the usual causes of hæmoptysis, said to be a valuable early symptom of syphilis of the pulmonary artery. Polycythæmia is present. The right side of the heart is enlarged, and X rays show dilatation of the pulmonary artery. After two to five years in this stage the patient dies of heart failure, with or without œdema. Autopsy shows lesions of the large and small branches of the pulmonary artery, interpreted as syphilitic. The lungs show chronic bronchitis and emphysema, and the right side of the heart is greatly hypertrophied. Arrillaga[1] thinks that a non-specific bronchitis, by increasing the strain on the pulmonary artery, localises the syphilitic process there, while Escudero[6] holds that in true Ayerza's disease the bronchitis is also syphilitic.

The clinical picture is obviously similar to that of heart failure secondary to chronic bronchitis with emphysema. The intense cyanosis, out of proportion to the other symptoms, has often been noticed. Escudero himself says that all cases of chronic lung disease with heart failure are very cyanosed and are therefore *cardiacos negros* but, in the absence of the typical syphilitic lesions in the bronchi and pulmonary arteries, are not cases of Ayerza's disease; while the lesions of Ayerza's disease may occur in patients who are not *cadiacos negros*. He says that Ayerza's disease can be distinguished from the heart failure of simple emphysema by the presence of polycythæmia and hypertrophy of the right side of the heart, a statement with which it is difficult to agree, since cyanosis of whatever origin may be associated with polycythæmia, and right heart hypertrophy is a commonplace in autopsies on cases of heart failure secondary to simple emphysema.

ÆTIOLOGY.

Although in some of the cases reported, such as those of Konstam[10] and Hare and Ross,[7] the pulmonary artery lesion is probably syphilitic, while in others, such as that of Warthin,[19] the syphilitic origin is proved by the discovery of the *Treponema pallidum* in the lesion, yet in many cases the part played by syphilis is very doubtful. In particular some French authors, such as Tremolières,[17] Caussade,[3] and Laubry,[11] have described cases in which endarteritis of the small branches of the pulmonary artery was found in patients with mitral stenosis and no clinical evidence of syphilis and in the one case where this was mentioned with a negative Wassermann. Syphilis was diagnosed because of the nature of the arterial lesions, though this alone seems inadequate, since endarteritis obliterans may occur in many conditions other than syphilis. In the following case there was very marked endarteritis of the smaller pulmonary artery branches in a case of mitral stenosis where there can be no reasonable suspicion of a syphilitic factor.

CASE 1.—A woman, aged 24, at her death in September, 1929, had her first overt attack of rheumatic fever at the age of 14. She became short of breath in 1925, and a little later her ankles began to swell. She became steadily worse until she was admitted to the Queen's Hospital under Dr. J. G. Emanuel in September, 1929. She was pale and somewhat cyanosed. There was great dyspnœa and marked œdema with ascites. The heart was regular and showed the signs of mitral stenosis. She died six days after admission.

Autopsy showed the body of a small poorly developed young woman, with marked œdema of the legs and ascites. The lungs were congested and œdematous. The main intrapulmonary branches of the pulmonary arteries showed fatty atheromatous patches. The heart weighed 420 g. and was greatly enlarged owing to dilatation of all the chambers especially the auricles, and hypertrophy of the ventricles, especially the left. There was a typical mitral stenosis, the orifice being reduced to a small slit. The aortic cusps were a little thickened, but the valve was competent. The aorta was narrow, and its intima was smooth and showed no lesion of any sort. There was no evidence of recent rheumatic infection. The organs showed chronic venous congestion.

Microscopically, the small branches of the pulmonary artery were greatly thickened (Fig. 1). There was much peri-arterial fibrosis. The media was rather thickened. The intima was greatly thickened and was often thicker than the media. It consisted of fibrillar, fairly cellular connective tissue, sometimes with multiplication of the internal elastic lamina. Some of the vessels were almost completely occluded. The medium-sized vessels showed similar but less marked changes, and the intimal thickening was less uniform. The lung tissue showed much peribronchial fibrosis. The alveolar walls were thickened and there was much catarrh of the alveolar epithelium. There were many areas of collapse with fibrosis and much proliferation of the alveolar epithelium. The appearances were suggestive of a chronic pneumonic process, perhaps of rheumatic origin.

Thrombosis of the Pulmonary Artery.

Thrombosis may occur in syphilitic aneurysms of the pulmonary artery, and is common in the small aneurysms frequently present in tuberculous cavities. It may also occur in syphilis of the pulmonary artery without aneurysm formation. Such cases have been described by Cheney [4] and Clarke.[5] Laubry and Thomas [12] describe a type of syphilitic pulmonary artery disease in which the symptoms from the onset are those of thrombosis with infarction. The thrombosis usually involves the small arterial twigs, but in McPhedran and Mackenzie's case[14] the larger branches were thrombosed, though here the syphilitic nature of the process was rather doubtful. Thrombosis of the small twigs may also occur in "primary sclerosis," as in Bacon and Apfelbach's case.[2] Occasionally pulmonary thrombosis is due to the invasion of the artery by tumour. In the case of a youth of 18 suffering from carcinoma of the testicle, with secondary deposits in the lungs, the branch of the pulmonary artery to the left lower lobe was plugged by thrombus. Microscopically, the artery wall was seen to be infiltrated by growth and many tumour cells were mixed with the thrombus in the lumen. It is noteworthy that this patient was pale, not cyanosed, and showed no special respiratory embarrassment. A rare form of thrombosis of small twigs in pneumonia has been described by Keefer.[9] The thrombosis causes areas of "aputrid pulmonary necrosis," which give the X ray appearances but not the symptoms of pulmonary abscess. Posselt[15] and Kauffmann [8] state that thrombosis is not very uncommon in pulmonary atheroma secondary to emphysema and mitral stenosis, and several examples of thrombosis of fine twigs have been recorded in the cases of endarteritis complicating mitral stenosis. Laubry and Thomas [11] attribute the hæmoptysis which is so common in mitral stenosis to thrombosis of small branches of the pulmonary arteries.

Thrombosis of large branches in cases of "secondary pulmonary artery sclerosis" seems not to have attracted much attention, and therefore the following cases seem worthy of record, especially as in one of them the thrombosis seemed to be the immediate cause of death.

CASE 2.—A woman of 58 had had a winter cough for years. For the last year she had become increasingly dyspnœic, and for a few weeks there had been increasing œdema of the legs. On admission she was very dyspnœic, cyanosed, and œdematous. The heart was enlarged (right border 2·7 and apex 4·5 inches from mid-line) and the lungs showed signs of chronic bronchitis and emphysema. She died six weeks *after admission*.

Autopsy showed the body of a fat woman with œdema of the legs. There were recent thrombi in the right femoral and left subclavian veins. The heart was enlarged (weight 530 g.) owing to hypertrophy and dilatation of the right ventricle. The valves were normal. The lungs showed chronic bronchitis and emphysema, with congestion and œdema. There was a large infarct in the right lower lobe. The main intrapulmonary arterial branches showed many patches of atheroma. The artery to the right lower lobe was almost completely blocked by pale adherent thrombus. The medium-sized vessels throughout the lung were extensively thrombosed. The other organs showed only chronic venous congestion.

Microscopically, the main artery to the right lower lobe shows change in all its coats. The adventitia shows hyaline fibrous thickening, with foci of lymphocytic infiltration. The media, except where it is thinned opposite the patches of atheroma, is of normal thickness. It shows much hyaline degeneration and its elastic fibres are much diminished in number, especially next to the intima. The intima is generally slightly thickened and shows numbers of typical atheromatous patches. The lumen is almost completely blocked by thrombus consisting chiefly of fibrin. The vessels of diameter 5–7 mm. show similar changes. Many contain old thrombus with early organisation (in growth of new capillaries and fibroblasts). The small arteries show perivascular fibrosis and hyaline intimal thickening, with narrowing of the lumen.

The pulmonary thrombus was obviously much older than that in the peripheral veins, so that it is improbable that it was of embolic origin. In none of the other cases was there any obvious source of embolism.

CASE 3.—A woman of 49 had had rheumatism in childhood. She had had a cough for years, with frequent slight hæmoptyses. For seven months she had been short of breath. She was fat, very dyspnœic, and cyanosed. The arms and legs were œdematous. The pulse was rapid but regular. The heart's apex was 7″, and its right border 2″ from the mid-line. There was an apical systolic murmur. The X ray showed a dense shadow in the lower half of the left lung field. She died a week after admission.

Autopsy showed the body of a fat œdematous woman. There were a few ounces of serous fluid in the pleuræ. The lungs were congested and œdematous, and showed chronic bronchitis and emphysema. There were hæmorrhagic infarcts in both lungs. There was a recent clot in the artery to the right lower lobe, and old adherent thrombus blocked the artery to the left lower lobe. The heart (weight 540 g.) was enlarged owing to hypertrophy and dilatation of both ventricles, especially the left. The myocardium showed patchy fibrosis. The mitral cusps were short, thick, and stiff, but the orifice admitted two fingers. There was marked coronary atheroma. The other organs showed chronic venous congestion.

Microscopically, the artery to the left lower lobe shows hyaline degeneration of the media and uniform hyaline intimal thickening, without atheromatous patches. The lumen is occluded by thrombus, old, fibrinous, and showing early organisation with the ingrowth of new capillaries at the edges; it is more recent in the centre. The small arteries show marked fibrous intimal thickening, with narrowing of the lumen. The lung tissue shows emphysema and congestion.

CASE 4.—A man of 58 was suddenly seized in July, 1927, with dyspnœa, which has persisted ever since. On admission in February, 1929, he was orthopnœic and generally œdematous. The heart's apex was 5½″ from the mid-line. Auricular fibrillation was present. There were signs of bronchitis, with blood-streaked sputum. He died four days after admission.

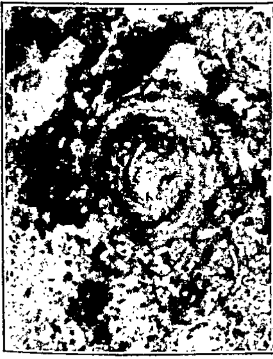
Autopsy showed moderate œdema of the legs and marked ascites. The lungs were congested and œdematous, and showed chronic bronchitis and emphysema. The pulmonary arteries were dilated, with many atheromatous patches and a little adherent clot in the main branches. The heart (weight 680 g.) was much enlarged owing to hypertrophy of both ventricles, especially the left. The valve cusps were normal, but the mitral and tricuspid rings were much dilated. The coronary arteries showed much atheroma. The other organs were congested.

Microscopically, the large branches of the pulmonary artery show typical atheroma. Some are completely blocked by thrombus, old at the edges, recent in the centre, and showing early organisation, with the ingrowth of new capillaries. A branch about 5 mm. in diameter, leading off from one of these, is blocked by organised and recanalised clot (Fig. 2). The small arteries show some intimal thickening.

CASE 5.—A man of 56 was admitted to the surgical side of the hospital with symptoms of carcinoma of the stomach. There was no note as to his chest condition, and no mention of cyanosis. He died two weeks later, without operation.

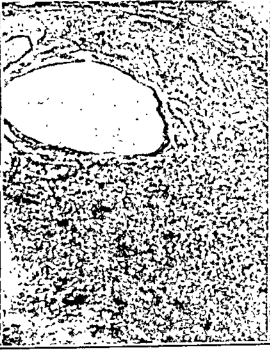
At autopsy, the lungs showed marked chronic bronchitis and emphysema. Near the apex of the right lower lobe was a small wedge-shaped area resembling an imperfect infarct. The pulmonary arteries were a little dilated and showed a few atheromatous patches. The branch to the left lower lobe contained a little ante-mortem clot. The branch to the right lower lobe was blocked by firm adherent thrombus. The heart showed little change. There was a diffuse carcinoma of the stomach.

FIG. 1.



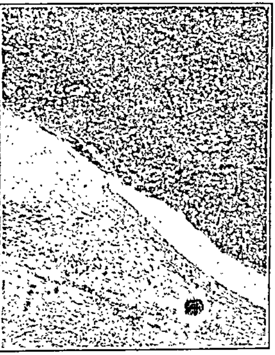
CASE 1.—A small pulmonary artery showing much intimal thickening and narrowing of the lumen. There is much pulmonary fibrosis. Stained with van Gieson and Weigert's elastic tissue stain. (×120.)

FIG. 2.



CASE 4.—Portion of a pulmonary artery 5 mm. in diameter, with lumen blocked by thrombus, most of which is converted into vascular fibrous tissue. Mallory's connective tissue stain. (×35.)

FIG. 3.



CASE 7.—Large pulmonary artery. Shows portion of an atheromatous plaque. Lumen blocked by thrombus which, over the patch of atheroma, is beginning to organise, as shown by the presence of numbers of capillaries. Mallory's stain. (×70.)

Microscopically, the large branches of the pulmonary artery show patchy atheroma, and many contain old thrombus showing early organisation with ingrowth of new capillaries. The small arteries show little change.

CASE 6.—A woman of 46 had had cough with blood-stained expectoration for 30 years, dyspnœa since 1915, and a sudden increase in the dyspnœa, followed by several large hæmoptyses, in 1921. On admission in May, 1928, she was orthopnœic, cyanosed, and very œdematous, with ascites and bilateral pleural effusions. The apex-beat was 4½" from the mid-line. There was an apical systolic murmur. Auricular flutter was present. She died on June 16th.

At autopsy the heart weighed 570 g. The left auricle was dilated and hypertrophied. The left ventricle was about normal in size; the right was very greatly dilated and hypertrophied, its wall being much thicker than that of the left. The mitral valve showed extreme button-hole stenosis. The pulmonary arteries were dilated and thick-walled, and showed many atheromatous patches. A thrombus about 1½" long, ¾" broad, and over ½" thick was present at the beginning of the artery to the right lower lobe, and greatly narrowed its lumen. Its surface was smooth, and it was very firmly adherent. It was evidently of very long standing.

Microscopically, many of the small branches of the pulmonary artery appear normal, but some show fibrous intimal thickening. No histological examination of the thrombus was made, as the lung was kept for a museum specimen.

CASE 7.—A man of 60, the hospital carpenter, had had chronic bronchitis for many years. For a few months he had been slightly dyspnœic on exertion. On the morning of Dec. 5th, 1928, he was much more dyspnœic than usual, but he went to his work at the hospital, where after an hour he "fainted." He was seen within ten minutes by the house physician on duty, who found him collapsed and pale, with a feeble but slow pulse. Half an hour later he was much better. His temperature was 96° F., his pulse-rate 70, and his respiration-rate 32. The pulse was feeble. The apex-beat was 4½" from the mid-line. There was never any cyanosis. He had four similar attacks during the day, and died in the last.

Autopsy showed the body of a thin old man. The pericardium was adherent to the front of the left ventricle. The heart (weight 370 g.) showed slight hypertrophy of both ventricles and dilatation of the right ventricle and auricle. The coronary arteries were atheromatous. There was no thrombus in the heart, and none was found in the peripheral veins. The lungs showed chronic bronchitis and great emphysema. The pulmonary arteries were dilated and atheromatous. The branch to the right upper lobe was blocked by firm adherent thrombus beginning about 2" above the origin and extending for about 2". The branch to the lower lobe was blocked for about 2" by firm adherent thrombus. The branch to the left lower lobe was blocked by a softer, smaller, and more recent thrombus which, however, was also adherent and obviously ante-mortem. The branch to the upper lobe contained only agonal clot.

Microscopically, the artery to the right upper lobe (Fig. 3) shows typical atheroma. The lumen is completely blocked by thrombus, old at the edges, more recent in the centre, showing early organisation with the ingrowth of new capillaries and fibroblasts. The small branches show comparatively little change.

Comment.

Several examples of endarteritis obliterans of the small branches of the pulmonary artery associated with mitral stenosis, such as occurs in Case 1, have been described in the French literature. In Case 1 there was no evidence of syphilis, and although most of the French authors attribute their cases to syphilis, they adduce no convincing evidence. In Case 1 there was a very marked chronic pneumonic process, possibly of rheumatic origin, and it seems not unreasonable to suggest that this was the local chronic inflammatory process which determined the occurrence of the endarteritis. It seems possible that the early death from heart failure with a normal rhythm might

NOTES ON THE CASES.

CASE 3.—This man complained of sexual impotence. He had been suffering from a recurrent anal fissure for many months. The cure of the fissure completely cleared up the impotence.

CASE 6.—This man had been unable to move except with great care for more than three years. In his last letter he says that at the age of 72 he now runs to catch an omnibus.

CASE 8.—There was a large hysterical element in this woman. Since her treatment she has had no acute pain, but she refuses to believe that the anus is now normal. As she seems to enjoy treatment she is being treated by an Abram's Box. In reply to a questionaire she says that she has no pain but is "conscious of her rectum." She has great faith that the Abram's Box will be of assistance, more especially as whatever local treatment she has is being enforced by "treatment directed towards the spleen!"

CASE 9.—This woman had previously been treated for internal hæmorrhoids by injections of carbolic in oil. She had found this treatment exquisitely painful. Whether it played any part in the later production of her fissure I am unable to say.

CASE 10.—This woman received no benefit from her first injection, and before the second injection I gave her a local injection of procaine and to some extent stretched the rectum with my fingers. I do not think that this divulsion, which obviously could only be lightly performed, played any part in the ultimate cure of the fissure.

CASE 13.—This man never had any pain until half an hour after defæcation. He then had acute pain for over an hour, and he had tried treatment by suppositories, ointment, and diathermy. One injection has led to his complete, and apparently lasting, cure.

It is hoped that in course of time more reports will be published on the effect of this method. It is only when many more reports are to hand that we shall be able to say whether it will hold the field. Meanwhile it is permissible to stress once again the pain which anal fissure can cause. Although, perhaps, in the majority of cases this is short-lived, in some cases it will last for seven or more hours, and will vary in its intensity from a local ache, always described as resembling toothache, to an excruciating agony. Such a small local lesion can affect not only physical activity but, if left untreated, gives rise to chronic constipation, general ill-health, and neurasthenia. Like the injection treatment of hæmorrhoids the treatment here advocated is ambulatory, and, carefully performed, has no contra-indications.

CLINICAL AND LABORATORY NOTES

AN UNUSUAL CASE OF TETANUS.

BY T. H. G. SHORE, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO THE SOUTH DEVON AND EAST CORNWALL HOSPITAL, PLYMOUTH.

IN the case here related tetanus toxin gained access through an inoculation site within the cavity of the nose, and consequently the symptoms were of the type described as cephalic or hydrophobic tetanus, but with certain modifications. There was never any real question of hydrophobia, though the possibility crossed one's mind at an early stage. Inability to swallow was due simply to pharyngeal spasm without any actual horror, and salivation was absent.

The patient was a boy, aged 3, the son of a publican, who was brought to Mr. C. S. C. Prance on account of difficulty in swallowing. He had been running about and playing as usual until the day he was brought, though the difficulty had been developing gradually for four days. During this time slight twitching of the right side of the nose and mouth had been noticed. There had been no complaint of sore-throat.

When first seen the child was extremely nervous and resented any examination, but trismus was at once observed making it impossible to examine the throat. On admission to a nursing home the temperature was 99·2° F. and the pulse-rate 134. The right palpebral fissure was smaller than the left; the pupils were equal and reacted normally. There was some rigidity of the neck, which, however, was easily overcome. Tendon reflexes were all very brisk, but were equal on the two sides. There were no enlarged lymph nodes in the neck, and nothing on which to comment in the condition of the heart, lungs, or abdominal viscera. The urine was free from albumin throughout. The throat and nose were examined under an anæsthetic, and a crust was removed from the right nostril. Though nothing else was found cultures were made which proved negative to diphtheria. During induction of the anæsthetic the child had a severe convulsion with general rigidity and cyanosis.

On the following day generalised spasmodic convulsions were easily provoked, during which the teeth were firmly clenched, the arms, legs, and back became rigid, the head was retracted, and the position of opisthotonos was assumed. The chest was fixed in the inspiratory position and cyanosis became extreme. The tongue was bitten once and flatus was passed, but never urine. After two or three minutes the spasm passed off, air was admitted to the chest, and cyanosis abated, but some degree of rigidity remained. The risus sardonicus was present. One such convulsion occurred during the night and another was observed on the morning after admission; the diagnosis was considered sufficiently definite.

Lumbar puncture was performed and 3000 units of antitoxin were injected, a further 3000 units being given subcutaneously. The fluid withdrawn presented no abnormality but was under considerable pressure, 30 c.cm. being obtained in a very short time. After washing out the rectum grs. 20 of chloral hydrate were given in saline, and were retained. Similar doses of chloral were given each night, and occasionally by day as well, and on five occasions it was necessary to give morphia in doses up to gr. 1/8. For the first two days the only nourishment was glucose by the rectal route, but on the third day the spasm in the masseters relaxed enough to attempt oral feeding, which became easier as time went on, and fluid feeds up to 8 oz. soon became possible. At first attempts to feed by the mouth induced spasm of the pharynx. All sources of external irritation were removed by darkening the room, putting down a thick carpet, preventing noisy closure of the door, and so on.

Serum was given daily for five days intrathecally, subcutaneously, or both, and convulsions were notably fewer after its administration, and on some days were completely absent. The slight general rigidity, however, persisted. After the first day all tendon reflexes were abolished. The temperature varied between 101·8° and normal, and the pulse-rate between 144 and 88. There was never any anxiety on the score of heart failure though frequently the convulsions were alarming. On the ninth day after admission, as spasm was still present, it was decided to explore the nose again on the assumption that the site of inoculation was in the right nostril. A general anæsthetic was given, and after the removal of several more crusts Mr. Prance found a small linen-covered shirt button fairly firmly impacted beneath the inferior turbinate.

Spasm was relaxed in a few hours, there were no more convulsions, and from now onwards there was no further anxiety for the future. No more serum was given and in five days—the 14th after admission and the 18th from the first symptom—the child returned home. Convalescence was rapid, and when seen a month later the boy seemed quite well except for a slight shuffling in his gait. The tendon reflexes had returned.

It is to be regretted that a more thorough examination of the nose was not made sooner; had it been made the duration of the illness would have been shortened. Failure to isolate *Bacillus tetani* from cultures was disappointing, but I am confident of the correctness of the diagnosis, quite apart from the control of the symptoms obtained by administration of the appropriate serum; 21,000 units were given and no rash followed.

The points which make the case worth recording are: (1) Age of the patient. According to most authorities the chances of recovery at the age of 3 are few. (2) Site and vehicle of inoculation. Although children will insert all sorts of foreign bodies into the nostrils I can find no other record of tetanus arising in this manner. (3) The incomplete picture of cephalic tetanus. Stiffness of the neck and jaws were present but there was no paralysis of the muscles supplied by the facial nerve. This, when present, is supposed to be due to compression of the swollen nerve in its bony canal. The site of inoculation was in the area of supply of the second division of the fifth nerve, and the only effect on the facial nerve was one of stimulation, shown by twitching of the nose and angle of the mouth before spasm became general, and narrowing of the palpebral fissure by stimulation of the orbicularis palpebræ. (4) Complete cessation of symptoms after removal of the cause. (5) Absence of nasal discharge which would have pointed more clearly to it.

A CASE OF PULMONARY SARCOMA.

By O. W. Roberts, M.D., M.S. Lond., F.R.C.S. Eng.,
ASSISTANT MEDICAL SUPERINTENDENT, ST. GILES'S HOSPITAL, CAMBERWELL.

A MARRIED woman, aged 35 years, was admitted to St. Giles's Hospital on Dec. 27th, 1929. She had enjoyed normal health until a fortnight before admission, when she had felt "run down" and had begun to have headaches. On admission she complained of severe headaches, general weakness, and impairment of memory; apart from these she had no symptoms. Clinical examination suggested a right-sided cerebral tumour associated with rapidly increasing intracranial pressure. A decompression operation was suggested, but the onset of signs of pulmonary œdema and the presence of dullness on percussion with absent breath sounds over the posterior part of the right lower lobe contra-indicated surgical interference. Intracranial symptoms increased and the patient died on Jan. 12th, 1930, one month after the onset of the first symptom.

Post-mortem examination.—The whole brain was œdematous and the convolutions were flattened. On section the cerebral and cerebellar hemispheres were found to be studded with numerous nodules varying in size from a pea to a plum. The nodules were situated in the white matter of the brain, being separated from the cortex by a narrow zone of white matter. Macroscopically they appeared to consist of soft vascular tissue which could be shelled out quite easily from the white matter, leaving a smooth depression. The larger nodules contained pus-like fluid from which a pneumococcus was cultured.

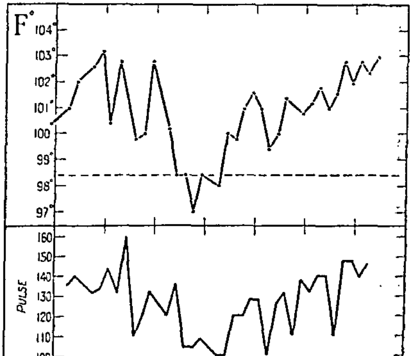
The lower lobe of the right lung was adherent to the diaphragm and to the chest wall posteriorly; on section a hard mass of new growth having irregular edges was found in the posterior part of the right lower lobe. Dilated bronchi containing purulent material were found in the tumour, and the macroscopic appearance suggested bronchial carcinoma. The other organs were apparently normal, and although a careful search was made no other deposits of new growth were found. Microscopic examination of specimens from the brain and lung showed a round-celled sarcoma.

The interesting points in this case are: the extremely short clinical history, the absence of any lung symptoms, and the distribution of the metastases. Intracranial abscesses complicating intrathoracic suppuration usually show a similar distribution to the metastases found in this tumour.

CEREBRAL HÆMORRHAGE FOLLOWING MENINGITIS IN A CHILD.

By L. I. M. Castleden, M.D. Lond.,
ASSISTANT MEDICAL OFFICER, HIGHGATE HOSPITAL.

"BEFORE the fifth decade cerebral hæmorrhage is rare," observes Osler, who further states that Holt had seen only one case under 10 years of age. In an investigation recently undertaken at the Hospital for Sick Children into cerebral hæmorrhage in children under 12, Sheldon [1] was able to find only 50 cases in his analysis of 10,150 consecutive autopsies. The comparative rarity of the condition therefore seems to justify the publication of the following notes of cerebral hæmorrhage in a child 1 year of age, additional interest being lent to the case by the fact that meningococcal meningitis was the possible precursor.



Temperature and pulse chart from admission to hospital on April 20th.

ACCOUNT OF THE CASE.

A boy, aged 1 year, was admitted to Highgate Hospital on April 20th, 1930, with a history of persistent vomiting and obstinate constipation for three weeks. During the preceding few days the child had frequently put his right hand to the right side of his head. On the day before admission there had been twitching of the left side of the face and of the left arm. There had been no vomiting or convulsions.

The birth had been Cæsarean. There had been no previous illness and the child had been quite well up the onset of vomiting. There was no family history of tuberculosis or venereal disease.

On *examination* the child was conscious, well-developed, and pale, but not dehydrated. The head was retracted and turned to the right. The frontal veins were somewhat prominent. Occasionally he put his right hand to his right ear, and he resented being touched or moved. There was no external evidence of trauma. The mouth, throat, ears, and mastoid regions were normal. A few small, firm, discrete glands were palpable in the posterior auricular and suboccipital regions of both sides. No abnormal physical signs were detected in the examination of the heart, lungs, or abdomen.

---

[1] Sheldon, W. P. H.: Quart. Jour. Med., 1926–27, xx., 353.

The head was retracted, with rigidity of neck and back muscles. The pupils were equal and reacted to light. There was slight internal strabismus of the left eye, the ocular movements and vision being apparently good. There was left hemiplegia, maximal in the arm, which was adducted and flexed at elbow and wrist, with the forearm pronated. There was also rhythmical twitching, with a frequency of about 60 per minute, in the muscles of the left shoulder and arm and, to a lesser degree, in those of the left side of the face and thorax, and occasional arrhythmical twitches in the muscles of the left side of the abdomen and right side of the face. The reflexes were normal on the right side; on the left side those of the arm were uncertain but the knee- and ankle-jerks were definitely increased and the plantar response was extensor. Kernig's sign was negative. Abdominal reflexes were absent on the left side. The cerebro-spinal fluid was under increased pressure clear and faintly tinted yellow.

A provisional diagnosis of tuberculous meningitis, complicated by thrombosis in the right cerebral hemisphere, was made.

Course of Illness.—On April 21st, except that the twitching had lost its rhythmical character and occurred at infrequent intervals only, there was no change. Lumbar puncture yielded a fluid with the same characteristics as before. From this date until April 25th no alteration in the patient's condition occurred. Twitching then ceased entirely and he seemed slightly better. Lumbar puncture was not again performed. On April 26th he went into coma. The frontal veins were more prominent and there was no twitching. Both legs were now rigid, with increased tendon reflexes and bilateral positive Babinski's sign. The right abdominal reflexes were present and brisk, the left showed a very faint response. Physical examination was otherwise as before. On April 27th, after two generalised clonic convulsions, there was generalised rigidity, with conjugate deviation of the head and eyes to the right. Death occurred shortly afterwards.

Post-mortem examination.—Two soft enlarged glands were found at the bifurcation of the trachea. The thoracic viscera were otherwise normal, as were also the abdominal viscera.

The brain was very soft, with flattened convolutions and engorgement of the meningeal vessels. There were a few small extravasations of blood on the surface of the hemispheres. Along the course of the middle cerebral vessels there was a gelatinous semi-opaque exudate, in parts frankly purulent. Purulent exudate was also present on the under-surface of the cerebellum, involving the medulla and the roof of the fourth ventricle. The base of the brain was free from exudate. Several of the superficial veins of the cortex were thrombosed, being distended, firm, and of a reddish-maroon colour. This was most marked in the middle cerebral veins, and of these the right middle cerebral was the most affected. The ventricles were distended with blood-stained fluid. In the substance of the right cerebral hemisphere, in the region of the lenticular nucleus, there was a recent hæmorrhage which extended outwards to the cortex and inwards towards the internal capsule, but which had not ruptured either on to the surface of the brain or into the lateral ventricle. The basal ganglia of the left side, and the undamaged parts of those on the right side, were studded with minute petechial hæmorrhages, which were also found, though less abundantly, throughout the substance of the hemispheres.

No definite thrombosis of the cerebral sinuses was found. Both middle ears were normal. No aneurysm or other abnormality of the cerebral arteries was discovered.

Dr. J. G. Forbes made the following report on the cerebro-spinal fluid:—

Cerebro-spinal fluid.—A clear, slightly yellow fluid yielding a fine clot and a visible deposit of blood-cells. Films from the cell deposit show, in addition to red blood-cells, no marked leucocytosis. The lymphocytes are in excess of the polymorphonuclear cells, but there is no evident absolute lymphocytosis. The teased clot does not show abundant cells; no organisms were seen, and no tubercle bacilli were found after a long search. Albumin, a heavy trace = 0·14 per cent.; globulin, + +; dextrose, faint trace; colloidal benzoin reaction, negative; cultures sterile.

These indications are not obviously in favour of tuberculous meningitis, although it cannot be excluded. The case is possibly a post-basic meningitis which has passed the acute stage, but no evidence of meningococcal infection can be found. The cell content, however, does not clearly point to an inflammatory process. The unilateral character of the physical signs might be due to a lesion localised in the right hemisphere—e.g., meningeal hæmorrhage or thrombosis; this diagnosis would accord with the changes present in the fluid—viz., excess of protein, blood-cells, and serum.

On material sent for examination Dr. Forbes made the following report:—

Microscopical examination.—The cerebellum showed marked congestion of the meningeal vessels. The inflammatory cell exudate of the meninges was composed chiefly of polymorphonuclear cells. Among the inflammatory cells were seen diplococcal forms in units, suggestive of the meningococcus, but not identified in groups or masses, nor appearing intracellularly.

The substance of the optic thalamus was scattered with small hæmorrhages.

Sections of material from both right and left Sylvian fissures showed thrombosed vessels with extensive hæmorrhage undergoing organisation and studded with blood crystals. The exudate on the meningeal surface consisted chiefly of polymorphonuclear cells, apparently with diplococcal forms, as seen over the cerebellar meninges. No trace of tuberculosis was seen in any section.

The diagnosis is possibly meningococcal meningitis (post-basic), resulting in blood infection and invasion of the cerebral vessel walls, this giving rise to thrombosis and consequent hæmorrhage into the substance of the cerebrum.

DISCUSSION.

If intracranial hæmorrhage following birth injuries and postnatal traumata be excluded, then thrombosis of the vessels of the brain, or of the sinuses and their tributaries, is the most common precursor of cerebral hæmorrhage in children. This thrombosis is either marantic or infective in origin, the marantic variety occurring most commonly in the superior longitudinal sinus whilst the infective may occur in any situation as a sequel of septic or tuberculous processes, but is most usually seen in the lateral sinus following suppuration in the mastoid. For these reasons it is easy to see why the commonest situation of intracranial hæmorrhage in children is meningeal. Of Sheldon's[1] 50 cases, 28 were extra-cerebral and 22 intra-cerebral, though arterial hæmorrhage and hæmorrhage following trauma were included in his series. Cobb and Hubbard[2] published, amongst other cases, one of cerebral hæmorrhage in a girl of 2¼ years of age following thrombosis of pial veins. In this case otitis preceded the meningitis.

As the notes of the case here recorded show, it was an unusual one in that meningococcal meningitis was the possible precursor, and also in the fact that the site of the large hæmorrhage was intracerebral. From the distribution of the paralysis the primary vascular lesion must have been one which affected, in addition to the lenticular nucleus, the region of the genu of the right internal capsule, giving the greatest functional disturbance in the left arm, less in the left side of the face and trunk, and least in the left leg. Its location was of further interest in view of the rhythmical nature of the twitching observed early in the course of the fatal complication, interference with the large-celled pallidal or motor system of the lenticular nucleus "releasing" sub-pallidal motor centres and producing muscular hypertonicity and rhythmic tremor of the rigid limbs.[3] The absence of convulsions, except as an almost terminal event, is also in favour of the thrombosis being initially intracerebral rather than cortical.

Thrombosis in the right internal cerebral vein could have produced the syndrome observed, by stasis of the circulation and anoxæmia in the right basal ganglia and internal capsule, the damage to the vessels so caused being the determining factor in the hæmorrhage found in this situation post mortem. Thrombosis in this vein, spreading backwards, later reaching the great vein of Galen and so obstructing the left internal cerebral vein as well, would account for the ventricles being distended with fluid, a condition found when the veins of Galen are occluded; these veins are formed by the junction of the venæ corporis striati with the choroid veins. The distension of the veins on the forehead is hard to explain in the absence of thrombosis in the superior longitudinal sinus. In marantic thrombosis of this sinus it is common to find, together with convulsions, distension of the veins of the scalp and of the nasal veins, and epistaxis. Possibly the raised intracranial pressure interfered with the cerebral venous circulation sufficiently to produce this sign.

---

[2] Cobb, F., and Hubbard, J. P.: Amer. Jour. Med. Sci., 1929, clxxviii., 693.

[3] Purves-Stewart, J.: The Diagnosis of Nervous Diseases, 1924, London, p. 16.

Since the work of Charcot and Bouchard, the question of arterial cerebral hæmorrhage has been thoroughly investigated. Hæmorrhage from the capillaries and veins of the brain, however, seems to have received but little attention. The latter is either rare or is considered of small importance, the lesions being usually described as hæmorrhagic encephalitis. The encephalitis, if present, probably acts on the veins merely by thrombosis, hæmorrhage resulting from mechanical obstruction to the venous circulation, with increased venous pressure and local damage to the vessel wall from anoxæmia.

This case, then, suggests a rare complication of meningococcal meningitis and demonstrates the possibility of intracerebral hæmorrhage of venous origin at a site usually associated with arterial vascular lesions.

I wish to thank Dr. C. Thackray for permission to publish this case, and also Dr. J. G. Forbes for his kind consent to my including his pathological and histological reports from the London County Council Bacteriological Laboratory, County Hall.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

EXHIBITION OF CASES AND SPECIMENS.

At a meeting of this section held on April 17th the chair was taken by Mr. C. P. G. **Wakeley**, the President, who showed a case of old crush fracture of the lumbar vertebræ. The man, aged 47, had first been seen on March 3rd last, complaining of weakness and pain in the lumbo-sacral region for ten years. He was unable to pick up heavy objects from the ground. His only injury had been a fall at the age of 4. There was an old crush fracture of the third and fourth lumbar vertebræ, but no evidence of bone disease. Diathermy had been tried, but had made the pain worse. A week later, after resuming work, the pain had almost disappeared. The case showed that crush fractures did develop in children. The pain was probably due to osteo-arthritis. Mr. Wakeley also showed a large congenital lymphangioma in the face of a five-weeks-old baby which was doing well, and asked what, if anything, should be done. In his third case the patient was a woman aged 53, who had been operated on in 1902 for carcinoma of the right side of the tongue. The glands had not been infected, but the growth had been a squamous-celled carcinoma. The operation had not proved a mutilating one, and she was now in good health.

Mr. **Eric Crook** suggested that radium might be useful for the baby. Mr. Wakeley said he was inclined to wait, since these conditions sometimes cleared up. Sodium morrhuate had also been suggested.

Mr. C. W. G. **Bryan** showed a case of painless swelling on the sternum in a girl aged 8½. X rays showed much new bone formation at the edges of a rarefied area beneath the tumour. No fluid had been obtained by aspiration, and other investigations had given negative results. The tumour had considerably increased in size after two weeks' treatment by potassium iodide.—The **President** thought the tumour was tuberculous.

DISEASES OF THE COLON AND RECTUM.

Mr. J. P. **Lockhart-Mummery** showed five cases: a megacolon treated successfully by appendicostomy; a complete colectomy for adenomatosis; another case of adenomatosis with cancer; and two cases of rectal cancer cured by operation. The first patient had done very well as long as she had used the appendicostomy to wash out the bowel, but had relapsed when she allowed it to close. Reopening had again made her comfortable. In the second case the whole bowel had been involved up to the cæcum; the polyps in the rectum tended to recur, but could be controlled. The patient showed a remarkable family history, her mother and six aunts and uncles having died at an early age of carcinoma of the bowel. Her only other living relative also had adenomatosis. A similar family history had been traced in 13 cases, and they had all died of cancer. The rectal cases were two out of 58 operated on more than seven years ago and now alive and well.

Mr. **Crook** agreed that adenomatosis often ended in carcinoma, usually, he thought, at the lower end. Colectomy left behind the part where polypi formed, and possibly the site of cancer.

Mr. G. E. **Parker** asked to what extent the small bowel compensated in these cases, and whether the patients suffered from diarrhœa.

Mr. F. F. **Hellier** asked what was the relation between polypi and carcinoma.

Mr. **Lockhart-Mummery** replied that the lower end of the ileum dilated considerably. It would be ideal to remove the rectum too, but the ileum could not be implanted into the skin. He thought that all carcinomata of the bowel arose originally from simple tumours. Hyperplasia of the bowel showed itself, probably, as adenoma in early middle age. The growths in the rectum were more likely than others to become malignant.

LARYNGITIS IN SCARLET FEVER.

Dr. J. D. **Rolleston**, on behalf of himself and Dr. D. G. **Macpherson**, showed a case of tracheotomy for œdematous laryngitis in a woman with scarlet fever. The case had previously been mild, but after the sixth day the temperature had risen and adenitis had appeared. On the tenth day of the disease she had developed urgent dyspnœa, and tracheotomy had been performed in extremis. The wound had become very septic, and the temperature had continued high. The case had been further complicated by cellulitis of the neck and pleural effusion. The patient had twice received 40 c.cm. of antitoxin, but without benefit. The temperature had not returned to normal until the forty-sixth day of the disease, but she had finally recovered. The case was unique in Dr. Rolleston's experience; any serious involvement of the larynx in scarlet fever was very rare, and tracheotomy was now hardly ever performed in fever hospitals. Pleurisy was also rare in scarlet fever, and usually went on to empyema.

Dr. W. C. **Gunn** said that recovery was extremely rare in cases of this kind, and described a patient he had seen; death had been due to septic pneumonia associated with pressure on trachea and bronchi. He had seen quite a number of cases of laryngitis in the course of scarlet fever, but they had been due to associated infections and not to the scarlatinal streptococcus.—Sir **James Dundas-Grant** said that the free incision through the œdematous tissues of the neck had played its part in saving the life of this patient.—Mr. **Crook** thought it extraordinary that œdema of the larynx was not more common; œdema would be expected to track back from the inflamed glands.

Dr. **Rolleston** suggested that the reason was the reduced virulence of streptococci nowadays.

UNEQUAL PULSE: ANEURYSM.

Dr. D. E. **Bedford** showed a female patient, aged 49, in whom inequality of the pulse and pupils was associated with hypertension and aortic incompetence. The left radial and brachial pulses were scarcely palpable, and the blood pressure on that side was 100/75. The right radial and brachial arteries were thickened, and the blood pressure was 200/40. There was a similar difference in pressure at the knees. There were no signs of a collateral circulation. She seemed to have an occlusion of the left subclavian artery of at least ten years' standing. It was probably not syphilitic, since she had survived so long and the Wassermann reaction was negative. The only possibility seemed to be stenosis of the isthmus of the aorta, involving the left subclavian and left carotid orifices. There was no sign of aortic aneurysm on radiographic examination.

Sir **James Dundas-Grant** asked why the suggested condition should affect the left lower extremity.—Dr. F. **Stolkind** mentioned a patient with syphilitic aortitis who had survived over 20 years, and described a case of unequal pulse due to syphilis.—Mr. **Harold Edwards** showed a case of popliteal aneurysm six months after the Hunterian operation. The aneurysm had been very large and adherent. The result had been very successful.—Sir **James Dundas-Grant** remarked on the safety of the operation.

Mr. **Crook** showed a boy of 18 months who had been born with exomphalos, the cord containing a large portion of liver, but no intestine. The child had been left with wide divarication of the recti.

The **President** said he thought that the recti would come together in time.

Dr. W. L. **Hartston** showed a case of

GAUCHER'S DISEASE.

The boy was six years old, and had had a large abdomen from the age of 18 months. Two brothers were alleged to have had enlarged liver and spleen, one being stillborn and the other having died at the age of two. This boy was wholly pigmented a dirty brown, had clubbing of all the fingers, genu valgum, and pes plano-valgus. There was no ascites and no adenopathy. There was osteoporosis of all the skeletal bones, with marked thinning of the corticalis, but the pituitary fossa was normal. The skin showed increased pigment deposit in the basal-cell layer, and the blood-cholesterol was greatly raised—between 220 and 360 mg. per cent. Splenic puncture revealed groups of large clear cells without fat, like Gaucher cells.

Dr. **Helen Mackay** spoke of her difficulty in obtaining tissue by splenic puncture. She did not think this case was pure Gaucher's disease, as the patient was more backward than could be accounted for in this way.—Dr. **Alice King** said she had known other cases in which a family history had figured.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

At a meeting of this section on April 10th, with Mr. R. **Atkinson Stoney**, the President, in the chair, Mr. **Seton Pringle** reported two cases of

POPLITEAL ANEURYSM.

Both patients were elderly men with marked hardening of the arteries. In one, the Wassermann reaction was positive and in the other negative. In each case there was marked circulatory disturbance of the leg—œdema, enlargement of veins, and duskiness of the skin—with, in one case, gangrene of the tips of three toes. Both had very severe pain.

In the first case the femoral artery in Hunter's canal, enclosed in its sheath, was divided between two ligatures. In the second the lumen of the vessel was occluded by multiple ligatures and the sheath was injected with alcohol. In both, the femoral vein was divided between ligatures. The usual post-operative precautions were taken, and the condition of the circulation in the foot on the affected side did not give rise to any anxiety after the first few hours. Both aneurysms ceased pulsating; as soon as the ligatures were tied they rapidly hardened, and gradually decreased in size. Both patients, 15 and 4 months after operation respectively, are in good general health and able to get about.

The **President** said that such aneurysms were comparatively rare. It had been formerly taught that, if the main artery and main vein were tied up together, gangrene was almost certain.

Mr. W. **Pearson** said it was more difficult to get good results in pathological than in traumatic aneurysm. In a case of subclavian aneurysm, with a strongly positive Wassermann reaction, he had obtained an excellent result by distal ligation.

RUPTURED SPLEEN.

Mr. **Seton Pringle** also described a case of spontaneous rupture of the spleen, occurring in a healthy man who was riding round his farm. There was no history of even slight trauma. The patient was suddenly seized with very acute abdominal pain, slipped off his pony, and was found in a collapsed condition. On admission to hospital five days later it was thought that he had a minute duodenal perforation, with gradually extending extravasation. At operation the abdomen was full of blood, originating in a rupture of the spleen. The spleen was removed without difficulty, but the patient developed pneumonia and died.

Growth of Contributory Schemes.—Last year the weekly contribution scheme of the Royal Berkshire and Associated Hospitals Aid Committee produced £31,136, an increase of £1223, notwithstanding that membership is now limited to those who are not liable to income-tax. At the same time the administrative expenses have been reduced.—The Salisbury and District Infirmary League collected £12,750, an increase of £700.

REVIEWS AND NOTICES OF BOOKS

Irradiation with the Alpine Sun Quartz Lamp,

including some account of Luminous Heat Rays. By HUGO BACH, Geh. Sanitätsrat, Dresden, with the assistance of Dr. FERDINAND ROHR. English edition. Edited by R. KING BROWN, B.A., M.D., D.P.H. Slough: Sollux Publishing Co. 1931. Pp. 218. 10s. 6d.

THE first water-cooled quartz lamp was introduced by the Hanau Quartz Lamp Co. in 1906, and a few years later, in 1910, Dr. Bach designed the air-cooled mercury-vapour lamp which achieved immediate popularity and became one of the standard models used in the practice of actinotherapy. In this small manual Dr. Bach gives his reasons for preferring quartz light treatment to other forms of ultra-violet irradiation. In order to raise the ultra-violet output of carbon-arc lamps very strong currents must be used. Lamps using 30 to 70 ampères are necessary to obtain satisfactory clinical results. This increases the cost of treatment and requires special electrical installations. Dr. Bach grants that these powerful carbon-arc lamps give very good clinical results and that in the domain of surgical tuberculosis they may outclass a single quartz lamp in their effect, the quartz lamp emission containing only a small proportion of luminous heat rays. He himself prefers, however, to use the quartz lamp for the treatment of all clinical conditions and to supplement the emission of his mercury-vapour lamp with that of a Tungsten filament lamp. The excellent results which have been obtained in the Finsen Institute with powerful carbon-arc lamps in the treatment of surgical tuberculosis will make most actinotherapists hesitate to change the method of treatment at present in common use, but a parallel series of cases treated (*a*) with carbon-arc lamps and (*b*) with mercury-vapour lamps supplemented by powerful Tungsten filament lamps, would be of great clinical significance. Dr. Bach's contention that it is important to be able to graduate the percentage amount of the rays of various wave-lengths in the total radiation will apppeal to everyone anxious to advance the science of actinotherapy, and it is a step towards the use of monochromatic light in clinical practice.

The views of the author on the treatment of phthisical patients are of special interest inasmuch as he may justly claim to be one of the earliest pioneers in this branch. He believes that, in general, phthisical patients are only suitable subjects for irradiation if their condition is stationary or tending to latency; the exudative and open forms of pulmonary tuberculosis need sanatorium treatment. In this latter group of patients, whether at an initial or advanced stage of tuberculosis, irradiation is a useful adjuvant; appetite and sleep are promoted, and the general condition may show marked improvement. Where there is failure to produce protective and curative substances in response to treatment, radiation will be just as useless in preventing death as is any other measure. Dr. Bach gives the impression that it is difficult to harm a phthisical patient by ultra-violet irradiation, if this is conducted cautiously and erythema-production is avoided. This is not a view generally accepted in this country nor is it held by all continental authorities.

This manual will prove of interest to all experienced workers in actinotherapy; it is less suitable for the student or the beginner since it represents a one-sided statement of the subject and is, moreover, not quite up to date, the references being mainly to work published before 1925. Dr. King Brown's translation is excellent.

Handbook of Anatomy.

By JAMES K. YOUNG, M.D., F.A.C.S., late Professor of Orthopædics, Graduate School of Medicine, Pennsylvania University. Seventh edition, revised by GEORGE W. MULLER, M.D., F.A.C.S., Associate in Anatomy, Jefferson Medical College. Philadelphia: F. A. Davis Company. 1930. Pp. 400.

JUDGING from the number of editions published since it was first written, this book appears to be in some demand in the country of its origin. It seems to us to be a well-produced work, composed solely from the point of view of examination needs. It cannot be taken as an indication of the standard of anatomy in the United States, nor yet as a book of reference on the subject. With these reservations we may say that it seems to be a reliable and useful member of its class, although we deplore the substitution of Latin names for perfectly good and descriptive English terms; yet they are better than such horrible expressions as *linguad* and *dorsad to.* A short but useful section on dental anatomy closes the book.

Anatomie und Pathologie der Spontanerkrankungen der kleinen Laboratoriumstiere.

Edited by RUDOLF JAFFÉ. Berlin: Julius Springer. 1931. Pp. 832. With 270 illustrations. R.M.98 (unbound).

THIS book should be of great value to laboratory workers. It contains articles by 29 different authors, many of whom are well-known pathologists, and is under the general editorship of Prof. Rudolf Jaffé, who has himself made considerable contributions to the text. It deals exclusively with diseases which occur naturally among the four species—guinea-pigs, rabbits, rats, and mice. The results of experimental infection with these diseases are also dealt with, though not exhaustively. The first or "special" part consists of 563 pages on the normal and pathological anatomy and the histology of the various organs, including the blood. In the 70 pages devoted to the urinogenital system are included the anatomy and physiology of the genital cycle in rodents, the phenomena of ovulation, pregnancy, placentation, and the senile changes in the genital organs. A treatise on the endocrine glands occupies 40 pages, and 25 are given to the skin. The chapter on the sense organs occupies 82 pages, which seems disproportionately long; but the information would be difficult to find elsewhere. That on the nervous system, by Dr. B. Ostertag (50 pages), is a very useful contribution. The "general" part deals with infection due to bacteria, protozoa, viruses, and metazoal parasites. These infective agents are described in some detail, but not always completely, and reference is made to fuller accounts in more specialised treatises. This part also includes a chapter by Dr. Fr. Heim and Prof. Ph. Schwartz on spontaneous tumours in rodents. The section on bacteriology is written by Prof. O. Seifried, and that on trypanosomes and spirochætes by Prof. H. Schlossberger and Dr. W. Worms. Prof. J. Fiebiger deals with the other protozoal, worm, and arthropod parasites of each of the four mammalian hosts separately. There is also a chapter on normal and abnormal carbohydrate metabolism. The arrangement of the book has been difficult, and appears in some places to be rather illogical, but an excellent index makes it easy to find any given subject. The illustrations, macroscopic and microscopic, are well reproduced, and some are original. On the whole the descriptions of anatomy and pathology are clear and informing. Considerable familiarity with English, American, and French work is shown, and full references are given.

A work of this kind has been much needed, but, as Prof. Jaffé realises, the inclusion of the diseases of monkeys and birds, if not of dogs and cats, would have greatly added to its value. In the limited field which it covers it is without a rival, and its publication will be welcomed.

Elementary Biology for Matriculation and Allied Examinations.

By MARY E. PHILLIPS, B.Sc., and LUCY E. COX, B.Sc. London: University of London Press. 1931. With 282 text-figures. Pp. 465. 7*s.* 6*d.*

IF matriculation students have to know all that this book tells them about animals and plants they will certainly be armed with a comprehensive knowledge of biology. It is because the book is likely to appeal to more advanced readers that it deserves special notice. It is very well compiled; there is the due mixture of structure, function, and nature study, the text is clear and interesting, and the illustrations first-rate. Covering the range they do, the writers cannot be expected to have a specialist's knowledge of every detail; superficial burns are dangerous through chemical, not nervous, shock (p. 224), the tapetum of the cat's eye is hardly "metallic" (p. 235), the relation of iodine to goitre, as stated on p. 197, is unintelligible. But much more than this could be forgiven for the saying (p. 441) "to understand bacteria they must be looked at from their own point of view; they are not themselves concerned in being either public benefactors or public scourges; they are simply minute living organisms." If students are taught in that spirit, they are on the right road.

Physiological Chemistry.

Fifth edition. By A. P. MATHEWS, Ph.D., Carnegie Professor of Biochemistry, University of Cincinnati. London: Ballière, Tindall and Cox. 1930. Pp. 1233. 15*s.*

THIS book, of which the fifth edition is now before us, has the distinction of being the first text-book on biochemistry in the English language. The first edition was published in 1915, and must be regarded as the parent of the many hundreds of text-books now on the market. Whilst some of these later authors acknowledge the debt, some do not. When first issued the book was of small bulk, but the fifth edition is a large and heavy volume of over 1200 pages. We have praised the work before, and need repeat only that its great value lies in the fact that an unbiased opinion on any biochemical problem may be found in it. One or two criticisms must be made. The sections on internal secretion, particularly those on the sex glands, are out of date. The author shows little knowledge of work done outside America; thus œstrin is dismissed in a very few words, and the male hormone is barely mentioned. Again, the question of tissue respiration is not adequately dealt with in a book of this size. But in spite of a few omissions the book can be commended to students for a full and well-written account of modern biochemistry.

Die Fadenpilzerkrankungen des Menschen.

Second edition. By R. O. STEIN, Professor of Dermatology, Vienna. Munich: J. F. Lehmann's Med. Atlases. 1930. Vol. XII. Pp. 128. With 107 illustrations. R.M.12.

THE text of this well-known atlas of the human mycoses, which first appeared in 1914, has been amplified by 33 pages, but there has been no increase in the number of plates or illustrations, which remain as they were in the first edition. The text has been improved by a table of contents, previously omitted. This includes a brief description of the morphology of the fungi concerned, staining and microscopic technique, culture methods, animal inoculation experiments, immunity reactions, including skin tests, and the preparation of trichophytin. This section occupies only 16 pages, and is followed by a detailed and illustrated description of all the cutaneous fungus diseases common to man, their pathology, diagnosis, and treatment. Of particular interest is the section dealing with the mycotic eruptions (eczematous) of the palms and soles, and their clinical differentiation into disidrotic, squamous, and intertriginous forms. The immense number of alleged pathogenic fungi makes a standard nomenclature difficult, and it will be long before this special branch of dermatology can approach completion. The increasing frequency and recognition of these cases has resulted in the publication of many papers both in Europe and America during the last decade, and the classification here adopted cannot be regarded as in any degree final.

An Introduction to Medical History- and Case-taking.

By GEOFFREY BOURNE, M.D. Lond., F.R.C.P., Assistant Physician, St. Bartholomew's Hospital. Edinburgh: E. and S. Livingstone. 1931. Pp. 195. 5*s.*

Dr. Geoffrey Bourne has written this little volume to help the medical student beginning his clinical work in the wards. It is divided into five sections, made up of history-taking, physical examination, diagnosis, prognosis, and treatment. Those who remember their first bewilderment when confronted with patients in the wards will also remember the poor comfort that the standard medical text-books seemed to provide, and the need for some small practical manual to help them in the difficult task of taking histories. Fortunately or unfortunately, it is true that nothing can take the place of actual teaching in the wards as an introduction to clinical medicine, but Dr. Bourne has provided an admirable elementary guide to supplement bedside instruction. Bad history-taking is a fault that is not always due to slackness on the part of the student, though this is an assumption that chiefs find convenient when they do not wish to impute lack of a thorough grounding by medical tutors. This volume provides the framework on which the student can build. The teaching is somewhat dogmatic, but the student will find it simple, concise, and easy to read, and much of the practical advice would not be wasted upon his seniors.

THE LANCET.

LONDON: SATURDAY, APRIL 25, 1931.

THE CENSUS.

THE census of the population of England and Wales, to be taken on Sunday night, marks the 130th anniversary of the adoption in this country of this important instrument of government—a respectable age in these days of widely advertised defences against senility. Yet each successive decennial enumeration, and this is the fourteenth, bears none of the disturbing signs of approaching dissolution arising from old age, but exhibits, on the contrary, clear signs of growth and development, and of a design to attain to greater perfection and accuracy in the collection and presentation of the data. In the past, misguided people burdened with a sufficiency of ignorance have regarded the practice with disfavour, but if we are to judge from the numerous references to the forthcoming census in the daily press, to broadcast talks on various aspects of census-taking, and to other manifestations of like kind which have been brought under the public notice during the past few weeks, it would appear that the importance of the undertaking is at length to receive adequate appreciation.

Although the primary object of this periodical inventory is the accurate determination of the numbers, constitution, and local distribution of the country's most valuable asset, the results of the count may be, and have frequently been, applied to purposes far beyond the limited field envisaged by these fundamental requirements. On the eve of the last decennial census, in these columns, we briefly discussed the value of census data to workers in the fields of demography and preventive medicine, mentioning inter alia that the incidence of natality, fertility, disease, and mortality were phenomena largely dependent upon the age and sex distribution of a people, and indicating how the census furnishes the information indispensable to the proper interpretation of these and other manifestations. But while census reports are tools necessary to the scientific researches of the vital statistician and the epidemiologist, they have become no less indispensable in other fields of inquiry. Reference to the published results of successive censuses reveals a steady expansion in the amount and variety of census data, suggestive of an increasing demand for such information resulting from a realisation that these data are fundamental to every kind of investigation associated with the commercial, economic, social, and other activities of the nation. It is indeed impossible to over-estimate the value of these clear summary statements concerned with the eddying tides of humanity. They provide the keys to a better understanding of the complex causes underlying some of the occupational changes which may have been observed between one decade and another; enable the tabulation of information relating to unemployment, thereby revealing the character and extent of such social and economic disturbances; are a measure of the increase or decrease in the numbers of people of foreign birth resident in this country, and of their share in the national life; throw light upon the size and structure of families, the circumstances under which human beings herd together, and the changing conditions of residence in urban and rural areas; enumerate with accuracy the numbers of widows, old-age pensioners and other dependent persons, and enable the assessment of the relative proportions of the agricultural, manufacturing, or other activities of the people. These, and other equally important items of information made available by the application of the census method of enumeration, have proved a source of inspiration to countless investigators, have served to arouse thoughtful citizens to realisation of conditions or developments demanding remedial action, and have contributed both directly and indirectly to bring about silent revolutions which have culminated in furthering the physical and social welfare of the nation.

If the statesman, hygienist, economist, sociologist, or other worker desires to build effectively and without misdirected effort, he is compelled to-day to enlist the services of the results of the periodical counting wherein are presented faithful pictures of existing conditions. The regularity of the count permits the comparability of data at different periods of time, currents of movement may be traced, changes in welfare indicating progress or retrogression of the human stock comprising the wealth of the nation are readily observable, and in the light of such knowledge future action may be determined with surer promise of success. From the medical point of view the planning of the enumeration to be made on Sunday night introduces one feature of considerable importance—viz., the schedule provides for a record of the place of habitual residence of persons enumerated elsewhere than in their own homes. This is a commendable change which will permit the more exact determination of local populations and more reliable calculation of local mortality-rates. Deaths are registered in the registration sub-district in which they occur, but are tabulated according to the district of habitual residence of the deceased. Up to the present it has been customary after each census inquiry to allocate all enumerated persons to the area wherein they happened to be at the time of the count; the practice about to be introduced will provide for a very necessary correction of the denominator of the fraction involved in the calculation of mortality and other rates.

The Census Office of the Registrar-General may be likened to a vast national laboratory wherein workers are engaged in the assembly and classification of the multitudinous details relating to human units, and in preparing and publishing a variety of exact facts upon which sound judgments may be based. These orderly analyses are of profound importance in the present age of expert investigation wherein problems of every aspect of human activity demand fuller and more precise information than was formerly considered necessary. The increased use of these data so evident in recent years, and the growing desire for systematic knowledge manifested by thinking people, are not only tokens of progress and enlightenment, but are abundant testimony that the results of the decennial count provide an efficient barometer of human development.

◆

SYMPATHETIC RAMISECTION IN SPASTIC PARALYSIS.

THE value of sympathetic ramisection in spastic paralysis has been much disputed. A group of orthopædic surgeons and neurologists reported unfavourably on six cases operated on in this country by the originator of the operation, Mr. N. D. ROYLE,[1] but at the Winnipeg meeting of the British Medical Association ROYLE found a good deal of support from American and Canadian surgeons.[2]

A further study of 83 cases has now been published by W. B. CARRELL[3] who, with his colleagues, has performed 23 cervical and 60 lumbar ramisections in spastic paralysis. He has encountered great difficulty in estimating the effects of the operation, for other measures were often undertaken concurrently, but he thinks that in practice reasonable accuracy has been attained. The reflexes showed no modification, but the patients who showed most improvement had a relative increase in active joint range. No change was noted in fixed contractions or in contractions which develop on attempting motion or on excitation, but a paraplegic seemed to have better function in the leg with lumbar ramisection and obturator section than with the latter operation alone. No appreciable improvement was ever seen immediately after operation, but when the time came for the patients to go to the gymnasium they gave better response to tests there than they had done before operation. The gymnasium work could not be credited with all the benefit, for the same work on patients who had not undergone ramisection did not produce the same results. But in CARRELL's experience if it were necessary to choose between ramisection and Stoeffel operations with foot stabilisation, the two latter procedures would be more often indicated and give a higher percentage of improvement in a large group of cases. The age of the patient and the type of paralysis seemed to be of less significance in the result than the severity of the lesion and the mental development. In the lumbar group the average gain was 16 per cent.; in 14 cases there was no gain, and in these the average age was $9\frac{1}{2}$ and the mentality $63\frac{1}{4}$; while in 12 cases with more than 25 per cent. gain the age was $10\frac{3}{4}$ and the mentality $81\frac{1}{4}$. CARRELL points out that if ramisection produces results by release of impulses affecting striated muscle there should be some evidence of changed reactions, yet in 14 cases no changes were observed. There was a high percentage of improvement in patients on whom the operation was performed on both sides, but no corresponding improvement when a cervical operation was followed by a lumbar, or vice versa. In 12 cases ganglionectomy was substituted for ramisection, with slightly better results. The 23 cervical cases were disappointing; 11 cases were not improved, 6 showed 10–15 per cent., and 5 showed 25–40 per cent. improvement. CARRELL's conclusion is that there is something definitely useful in ramisection which may be added to but not substituted for other procedures in the treatment of spastic paralysis. The orthopædist is thankful even for 10–25 per cent. improvement in these distressing cases.

In an accompanying paper in the same journal W. K. LIVINGSTON attempts to rationalise the surgery of the sympathetic system by regarding smooth muscle hypertonus or spasm as the underlying common characteristic of a number of syndromes for which sympathectomy may be useful, the visceral pain group being due to abnormal changes in tonus of peripheral blood-vessels, the gastro-intestinal group to hypertonus of sphincters, and the vascular group to reflex diminution in blood-supply. He includes chronic arthritis in his third group, since the balance between wear and repair in a joint is dependent on adequate vascular response to function, and benefit has followed unilateral lumbar ganglionectomy in some of his cases. Many cases of obliterative endarteritis show an added element of spasm, he maintains, and sympathectomy will improve such cases. He suggests three ways of deciding whether or not a patient will benefit from operation. Oscillometry reveals an abnormal restriction in the amplitude of pulse oscillation, particularly after exposure to cold, while the fever test consists in the production of pyrexia and measurement of the vasomotor index or ratio between the rise in mouth temperature and the rise in temperature of the affected extremity. The best method, however, is to note the changes that follow selective injection of sympathetic ganglia with procaine hydrochloride; this is not difficult or dangerous, and it accurately produces for a time the results that may be expected to appear permanently after surgical excision of the ganglia. He considers that it should prove valuable in enlarging the field of sympathetic surgery.

◆

WILDER ANIMALS.

ON Saturday, May 23rd, will be opened to the public a new zoological park in which many of the animals at present in the gardens of the Zoological Society at Regent's Park can be seen living under more natural conditions. The park occupies an estate of 500 acres on the Chiltern hills between Tring and Luton, and is being made accessible from Watling-street by a new road leaving the street a little north of Markyate and crossing Whipsnade Heath. On this property four chalkpits have been excavated primarily to obtain materials for road-making, but with the ultimate object of serving as dens for the larger carnivora, and many coniferous trees have been planted to form backgrounds for panoramas; enclosures for bison, wolves, bears, wombats, marmots, and woodchucks have been completed; six panorama paddocks and an enclosure for kangaroos have been laid out. Since the property has been enclosed wild flowers have increased greatly and many orchids and other plants natural to the chalk region, but wholly or nearly exterminated, have been reintroduced, and native birds have nested there in increasing numbers. The park is thus to be a sanctuary for British wild birds and the flowers, trees, and shrubs natural to the region. The more important animals already at Whipsnade, many of them the gift of the Duke of BEDFORD, President of the Society, are camels, llamas, zebras, eland, bison, bears, wolves, muntjac, Chinese water deer, fallow deer, black buck, marmots, woodchucks, wombats, sarus cranes, rheas, pheasants, turkeys, geese, and swans. One consequence of the greater freedom given to the animals is the possibility of risk to visitors, who are warned that the Society disclaims responsibility for damage caused by too close an approach to the fences or barriers, or by any attempt to stroke or touch the animals. Children under 12 will only be admitted to the park on the condition that their guardians make themselves personally responsible for their safety.

---

[1] THE LANCET, 1930, ii., 127.

[2] Ibid., p. 645.

[3] Jour. Amer. Med. Assoc., March 14th, p. 849.

The opening of the Whipsnade park is but a logical extension of the aim to let the animals feel at home. To what extent this has been already carried out under the enlightened directorship of Sir PETER CHALMERS MITCHELL and his staff is not perhaps as well known as it should be. There has been a steady reduction in morbidity among all classes of animals in the Zoo. It has been taken for granted that rickets and allied bone diseases can be prevented, in animals as in man, by hygienic living. During the past year only 26 animals died primarily from rickets and osteomalacia: most of these arrived at the Zoo in rickety condition; in only three animals, including a monkey and a douroucouli, did the disease originate in the gardens. For some years artificial light has been installed in the monkey-house to supplement the sunshine to which all anthropoids are racially entitled. A study of the heading "Commissariat" in the Society's annual report reveals the variety of foodstuffs which are provided for the animals, ranging from vast quantities of staples such as hay (168 tons), oats (748½ quarters), locust beans (79 cwts.), horseflesh (269 tons), down to shrimps (2178 pints), sultanas (104 lb.), ant eggs (461 lb.), dried flies (709 lb.), and golden syrup (148 lb). Tuberculosis now accounts for a bare 3·4 per cent. of the total deaths in the Zoo, and the only tuberculous lesions found in monkeys were in two individuals which died in quarantine a few days after arrival. Apparently no monkey or ape contracted tuberculosis in the gardens during the year. On the other hand, it is interesting to note that an old tiger died from tuberculosis of the lungs with extensive cavitation, and an Indian fruit-bat of eight years residence from intestinal tuberculosis. Respiratory diseases in general were fewer. Colonel A. E. HAMERTON remarks that the seasonal fluctuation in the mortality from diseases in this category corresponds with that of the human population living in northern cities. Seven birds died from bird malaria and five from heart disease. In other cases conditions were found analogous to those met with in human practice. Two mammals died from ureteral obstruction by renal stone. Hepatic disease caused 20 deaths, two of which were associated with gall-stones. New growths were found in five mammals and two birds; a grison died from cancer of the liver, and a mynah from cancer of the pancreas. Immunity from epidemic disease is maintained by the new isolation hospital on the north bank, the efficacy of which was tested on several occasions by outbreaks of cat distemper which were confined to a few isolated cases.

Under the more natural conditions at Regent's Park animals are continually breeding more freely, although the infantile mortality from various causes is still high. A baby sacred baboon was killed by a companion at six months old, a mother wolf destroyed five of her six cubs at four days old, and an American bison calf was accidentally killed by its father when 12 days old. Nevertheless the list of mammals successfully reared last year is very striking; it includes two pygmy hippopotamuses, a Californian sea-lion, a Canadian beaver, three lion cubs, wallabies, marmots, lemurs, and a host of hoofed creatures. What are the genetic opportunities of Whipsnade can hardly be forecast.

THE BRITISH SOCIAL HYGIENE COUNCIL.

A LECTURE was delivered on Tuesday, under the auspices of the British Social Hygiene Council, with the Duchess of Atholl in the chair, at the Marble Arch Rooms, London, on Social Hygiene and the Family, by Dr. Maurice A. Bigelow, professor of biology in Columbia University, who has been delegated to Europe to observe the development of social hygiene during the past ten years. Speaking from personal experience in the United States he described the introduction of social questions into the curricula of educational institutions and, in comparing the work of the British Social Hygiene Council with that of the analogous society in America, he pointed out that in both cases social hygiene meant social welfare, and the benefits to be derived were based upon the comprehension of sex. It became clear that Prof. Bigelow did not mean by the study of social welfare, concentration upon sexual problems, but upon family relations, the family being the expression of sexual activity. Society in America, he said, still regarded the family as a unit, the welfare of society being bound up with the safeguarding of that unit; and, alluding to the frequency of divorces in America, he found them not to prove opposition to the family unit idea but only unadaptability of the contracting parties, inasmuch as for the most part divorced people desired to marry again. While urging the inclusion of suitable biological instruction in the education of the young, he declared that the stories of misdemeanour at coeducational schools in America were grossly exaggerated, and said that whenever investigation had been made the untrustworthiness of the rumours had been patent.

ANNOTATIONS

APPLIED PHYSIOLOGY AND PSYCHOLOGY.

THE work of the London School of Hygiene and Tropical Medicine is far wider than its name implies, and brings it into intimate liaison with Government departments and other bodies. A little-recognised branch of its activities and one of great importance was described by Prof. Major Greenwood in a paper read before the Royal Society of Arts on Wednesday last—that is, its work for the immediate service of industry. The divisions of biochemistry, bacteriology, and medical zoology perform work of immediate value in improving processes of manufacture and soil conditions, but the work of the school towards the betterment of the hygiene of industrial conditions, while equally important, is much less widely appreciated. As Prof. Greenwood pointed out, the value of physiological research to labouring life is only just becoming apparent. The part which Sir Leonard Hill has played in applying the discoveries of the laboratory to the problems of the workshop will perhaps not be fully appreciated for a generation or so. It would be hard to exaggerate the increase of human comfort directly attributable to his simple katathermometer alone.

Moreover, the spirit of his investigations is far more important even than their result. Less than a generation ago the physiologist—in the words of Prof. Greenwood—was regarded as a rather unpractical person, much more interested in the twitching of frogs' muscles than the doings of men and women. The physiologist tended to despise the practical man and the practical man heartily returned the compliment. Sir Leonard Hill has taught that laboratory physiology is an instrument and not an end in itself, and that the proper ambition of a physiologist is to understand human physiology. It is the business of institutions such as the Keppel Street School, said Prof. Greenwood, to see that this liaison between the laboratory and the workshop shall never be broken. The number of trained investigators is still small, but the coördination of the school's work with that of the Industrial Health Research Board will increase it, and the organisation of the Medical Research Council has extended the liaison to branches other than those with which Sir Leonard Hill's name has been associated. The school has already secured one element of success in ensuring that entrants to the public health services receive a proper grounding in the applications of physiology.

The physiological aspects of industrial hygiene lead straight to the psychological aspects, which, according to Prof. Greenwood, have not yet found their Leonard Hill; they are equally important with the physiological aspects, and progress in one direction cannot be achieved without progress in the other. Fortunately, as Prof. Greenwood pointed out, the Industrial Health Research Board has realised this truth from the beginning and has devised a unique and highly promising combination of clinical and experimental methods of research. The school, for its part, has introduced the elements of clinical psychology into the curriculum for the Diploma of Public Health and has established a chair of medical and industrial psychology. Prof. Greenwood prophesies that the school will train workers whose efficiency as industrial psychologists shall not be inferior to that of the industrial physiologists. If its work in this direction is comparable with that which it has performed in other branches of hygiene and tropical medicine, there need be no anxiety for the future of this new and very important enterprise.

MASTOID COMPLICATIONS IN SCARLET FEVER.

Dr. Kaisig has written a review of surgical complications in scarlet fever,[1] from which we have singled out the mastoid complications because of their frequency and importance. There are, she says, two main types of mastoiditis, differing clinically and pathologically; a very acute malignant type with extensive necrosis of the mastoid and early spread to the sinus and meninges (two cases in five years), and ordinary mastoiditis, as seen in conjunction with other specific fevers (35 cases). The cases of the latter she subdivides into three groups: according to whether it occurs during the first two weeks of otitis media (Group A); between the second and sixth week (Group B); or after the sixth week (Group C). Of the 14 cases in Group A, half showed fever, tenderness over the mastoid with redness and œdema, but all healed entirely with conservative treatment. The results of early surgery are poor, and one is well advised to wait till the inflammatory process has lost some of its urgency. Indications for operation are: (1) five to seven days' existence of mastoiditis without improvement in spite of a good discharge of pus and good local treatment; (2) abscess formation—swelling behind the ear and sagging of the posterior meatal wall; (3) the onset of septic symptoms. In Group B conservative treatment is of less importance, and operation should be performed if there has been any aural discharge for three weeks without any sign of improvement, with good treatment, and with a temperature practically normal. If there has been fever, which cannot be accounted for by any other focus of infection, operation should be done earlier, preferably at the end of the second week, since cases are found in which no signs of bone disease are present for three weeks and then suddenly marked local symptoms appear, extensive destruction being found at operation. Operation is required in all the cases falling into Group C. Many authorities never advise a radical operation in scarlet fever, but obviously a perisinous or subdural abscess will never heal with conservative treatment, and intracranial complications are very likely. This was present in 4 of 27 antrotomies recorded by Kaisig. Other advantages are that healing is quicker and later complications are avoided.

HOSPITAL COÖPERATION IN LONDON.

THE London Voluntary Hospitals Committee, whose origin was described in our correspondence columns last week, has now been in existence for a year, and the Central Public Health Committee of the London County Council has acceded to its wish to be consulted at an early stage on all matters of moment. It has been agreed on both sides that the machinery of Section 13 of the Local Government Act of 1929 should be used for exchange of information to the advantage of both the public and the voluntary hospitals services. No occasion has yet arisen to call together the area or other committees by whom the Voluntary Hospitals Committee is elected, as the

---

[1] Kaisig, E.: Monat. für Kinderheilk., 1931, xlix., 373.

London County Council decided at an early date to postpone the foreshadowed area organisation of their own services. The Committee has ascertained that there is no present likelihood of the Council departing from their existing practice of not making capital grants to voluntary hospitals. As regards maintenance, while the Council are not disposed to make grants for general maintenance, they are willing that payments for specific services required by the Council and rendered by voluntary hospitals to the sick poor should be continued, and that the application of this principle should be if possible extended. It will be remembered that this distinction was also drawn by Lord Cave's Committee. The Council have agreed to the Committee's request that as an interim arrangement contributions to voluntary hospitals of similar amounts to those contributed by the late guardians in 1929 should be paid for the year to March 31st, 1931, by the Council, on the understanding that the payments are without prejudice to whatever financial arrangements the Council may decide to make after that date.

The representatives of the Hospitals Committee at their last conference with the Public Health Committee urged that the Council should not insist on treating all patients chargeable to them if there were a choice of voluntary or Council accommodation. The Council took the view that it is their first duty to keep their own beds occupied, and that, while they cannot pay voluntary hospitals for services they can themselves supply, they adhere to the principle of grants for specific services rendered at their request. The provision of pathological laboratories at the Council's hospitals has been discussed with the Hospitals Committee. The Council have in mind as an ultimate ideal a well-equipped and adequately staffed laboratory in every general hospital, and one or more central laboratories for the specialised pathological work requiring expert knowledge and elaborate equipment. Their immediate proposals provide for the establishment of five "group" laboratories, suitably located, capable of dealing with the more specialised pathological work. The first of these "group" laboratories will be ready to function this month; two others will be completed in three or four months' time; the last two will be ready for use towards the end of this year. The late Metropolitan Asylums Board had already provided adequate laboratory services at the northern and southern "group" laboratories for the special hospitals, and also for the production of therapeutic sera at Belmont laboratories. The Committee agreed with the view that it was desirable to provide an adequate pathological service for every general hospital dealing with acute cases, and recommended that in the formation of "group" laboratories advantage should be taken of existing pathological departments of the voluntary hospitals, a suggestion which was not adopted.

At the desire of the Council the Hospitals Committee submitted a memorandum upon the use of municipal hospitals for medical education, and upon the methods of staffing at these hospitals. The appointment at municipal hospitals of resident house physicians and house surgeons would, it was pointed out, prove of value in the education of recently qualified men and women. Provision has already been made for such appointments. The Hospitals Committee also recommended that the present consultant services at municipal hospitals should be extended, and an advisory Board set up for the purpose of recommending consultants for appointment. The Council, however, decided to continue existing arrangements for a year and to reconsider them then. Opportunities for students to visit municipal hospitals for the purpose of studying diseases more often seen in those institutions than in voluntary hospitals are to be extended wherever possible. The shortage at teaching hospitals of obstetric beds for instructing medical students was discussed and the Council, while stating that the existing maternity units in their general hospitals were not of sufficient size to be suitable for teaching purposes and were fully used for the training of nurses, acquiesced in the principle of allowing the teaching of students in connexion with their maternity beds as and when satisfactory arrangements could be made. The Hospitals Committee also arranged two conferences with representatives of the Board of Control when the facilities provided by the Act were outlined for treating mental patients by voluntary hospitals.

BLOOD VOLUME AND CIRCULATION TIME IN BABIES.

AN interesting contribution to human physiology is to be found in the work of Dr. H. Seckel, in the Hamburg University Children's Clinic, on various aspects of the blood volume and circulation time in babies and young children. His latest paper[1] deals chiefly with circulation time and the minute-volume and stroke volume of the heart's output, forming a logical sequence to his previous studies[2] of total blood volume in normal and sick children from the early weeks of life up to 14 years. After a brief discussion of the various ways of investigating the circulation time in human subjects and the special disadvantages presented by most of them for pædiatric work, Seckel advocates the "histamine rash" method as most useful. In the doses he employs this substance is free from all risk, can be relied upon to produce reddening of the face, and has a purely local action on the capillary system. The total blood volume was estimated by a colorimetric method at the same time and the following represents a summary of the routine adopted.

All the children in the present series were young babies and the investigation was performed with the child fasting and lying quietly at rest. The exact number of heart beats for a full minute was counted by auscultation at the apex. Next, blood was taken from the heel for a hæmoglobin estimation and red-cell count. A red-cell count was also made in blood obtained from the longitudinal sinus and the colour-index and "red-cell volume" calculated. The volume of the circulating blood was then determined by injecting trypan-red solution into the longitudinal sinus, samples of blood being taken before the injection and at 3½ and 5½ minutes afterwards. Next, the blood volume was determined colorimetrically, as described in detail in Seckel's earlier papers. When this had been done, histamine was injected into the sinus in a dose of 0·001 mg. per kg. of body-weight, the solution employed being 1 c.cm. of a 1 : 1000 histamine solution in 100 c.cm. of Ringer's solution. The exact time of the beginning of a blush on the forehead was noted by two observers with stop-watches. One difficulty of this method lies in keeping the child quiet, because any screaming naturally reddens the face, but Seckel appears to have got over this in 90 per cent. of cases by "psychical diversion" or failing this, by use of the "dummy" or small feed.

In nearly 50 babies of from 1 to 15 months old, mostly quite healthy or slightly dystrophic, the average total circulating blood volume was approximately 8 per cent. of the body-weight. The circulation time, measured to the beginning of the appearance of the reddening of the skin, was about 15 seconds for the first year of life in healthy babies and this showed a remarkable constancy in certain cases where the experiment was repeated more than once. Seckel emphasises that he is describing the "minimum" circulation time by this method, for the "middle" or "mean" time referred to by other workers is approximately double this. This is important when the results obtained are used to calculate the minute and stroke volume of the heart. As Seckel points out, direct estimation of these factors is in practice quite impossible in babies, but the minute volume can easily be reckoned when the total blood volume and "mean" circulation time are known. The minute volume in the first year of life was found to lie between 160 and 170 c.cm. per kg. of body-weight, and in the second year round about 130 c.cm. as compared with an average for adults of about 75 c.cm. The stroke volume could likewise be calculated from a knowledge of the heart-rate and was found to be about 1·3 c.cm. per kg. The work performed by the heart can be shown by these figures to be relatively larger for these young infants than for adults. The very high figures for the size of the circulation in young babies seems to be directly associated with the intensity of the respiratory gaseous exchange at this age and represents the organism's response to the growing tissues' great need of oxygen. In severe anæmia, in fever, in pneumonia, and in congenital heart disease, for example, this mechanism breaks down, and Seckel is doing further work on blood volume and circulation time in these disorders.

WELFARE OF THE BLIND.

THE ninth report of the advisory committee on the welfare of the blind to the Minister of Health[1] gives the number of blind persons in England and Wales registered on March 31st, 1930, as 56,853. This is an increase of slightly over 4000 on the previous year, but the difference is probably due to improved registration or else to a more liberal interpretation of the necessarily somewhat vague definition of industrial blindness recognised. ("too blind to perform work for which eyesight is essential.") The report insists on the importance of obtaining proper medical evidence from practitioners specially skilled in ophthalmology before anyone is placed on the blind register. It may be suggested that even so the decision as to whether a particular applicant is or is not blind within the meaning of the Act is no easy one. There are many borderland cases and a degree of vision which may be quite useless for reading and writing may be of considerable service in other respects. It is not surprising that there should be a difference of opinion even among ophthalmic surgeons about such cases. Some would sign their certificates; others would not. There is a greater difference between such a case and one who is "stone blind" without perception of light than there is between a man who can merely count fingers with the best correcting glass and one who is just able to see 6/60 but finds it impossible to obtain any sort of employment on account of defective vision. Yet for the latter there is no State aid forthcoming while for the former there is much.

The report comments on the changes due to the Local Government Act of 1929 establishing a new system of grants and throwing upon the local authorities the duty of dealing with and subsidising the voluntary associations who carry out the work for the blind. A main part of this work consists in the provision and organisation of employment for blind workers. The proportion of the total blind population who are employed is 17 per cent. and the report states that there are large numbers of blind persons undergoing training now who will be ready for employment in the next few years. As there is considerable difficulty in disposing of the goods made it is maintained there is urgent need for the establishment of a central marketing board. A placement committee has been established by the National Institute for the Blind for the purpose of fostering the employment of the blind, especially in ordinary factories and workshops. It was found that the earnings (approximately 15s. a week) of blind workers employed in ordinary factories averaged about two-thirds of what sighted workers could earn in the same occupation.

MYELOID SARCOMA.

IT is becoming fashionable, and it is certainly convenient, to use the name "osteoclastoma" for the tumour which arises in the medullary cavity of bones and is composed of spindle cells with a good proportion of giant cells which resemble osteoclasts. It is generally considered a benign tumour and great numbers of cases have undoubtedly been cured by curettage or local removal. Evidence however accumulates that growths of this histological type cannot be trusted to remain indefinitely localised at their site of origin. In 1926 Drs. E. F. Finch and H. H. Gleave,[1] of Sheffield, published a very clear example of malignancy. A man of 49 had a spontaneous fracture of his femur in 1917. By 1925 the leg was useless and was taken off, and soon afterwards the patient began to spit blood. He died in 1926 with abundant secondary growths of typical histological structure in the lungs. Dr. S. C. Dyke, of Wolverhampton, has recently described another instance in the same journal.[2] A man of 25 had trouble in 1924 with his knee, supposedly following an injury. In 1925 the knee was explored and an osteoclastoma curetted from the patella. In 1929 after a fall the lower end of the femur swelled and the leg was amputated and by the end of the year he had signs of a number of secondary growths in the lungs and elsewhere. He died in 1930 and metastases were found in the scalp, lungs, kidneys, and mediastinal and peritoneal lymphatic glands; further secondaries appeared to be present in the ribs and spine but these were not confirmed histologically. The microscopical appearances of the secondaries in this case were not so typical, but among masses of necrotic and spindle-celled tissue small areas were found everywhere which had the classical structure of osteoclastoma. Yet a third case has been put on record[3] from St. Mary's Hospital by Dr. J. W. Orr. A man of 20 had his leg amputated for a growth of the lower end of the femur, diagnosed histologically as "myeloid sarcoma." He died six months later with many metastases in the lungs but not elsewhere. The secondaries showed a spindle-celled stroma with many typical osteoclastoma giant cells; there was, however, a certain amount of bone and a number of small giant cells bearing no resemblance to osteoclasts but suggesting foreign body cells. In another case, observed many years ago by Prof. Robert Muir in Glasgow, the secondaries in the lungs showed only spindle cells as far as they were examined. Some people may argue that, because the secondaries in some of these cases did not show an exactly typical picture, the tumours in question were not genuine *osteoclastoma.* This seems to be hardly a more reasonable position than to say that a tumour cannot be an osteoclastoma if it is malignant. Osteoclastomas will show a uniform and typical microscopical picture only so long as they are benign; with the onset of malignancy we should expect greater or less departure from the customary structure and should not be surprised if some cases, such as Dr. Orr's, show signs of kinship with osteogenic sarcomata. Clinically at any rate it seems certain that purely local treatment cannot be regarded as altogether safe.

THE VETERINARY BULLETIN.

THE Imperial Agricultural Research Conference of 1927 recommended the publication of a veterinary bulletin by the Imperial Bureau of Animal Health, a task previously undertaken by the Bureau of Hygiene and Tropical Diseases. The *Tropical Veterinary Bulletin* accordingly was discontinued with the issue of Dec., 1930, and in its place a new journal under the title of the *Veterinary Bulletin* is to appear quarterly, the first issue of which is in our hands. It will deal with all aspects of animal health in so far as they relate to original research and administrative control, but will not deal with clinical material from the point of view of the practitioner. The ground covered will be wider than that of the bulletin whose place it has taken, for the animal diseases of temperate climates will receive full consideration, as well as such cognate matters as mineral and plant poisoning in animals. This first number contains 96 pages admirably arranged and printed but for the fact that the line is more than 5½ inches long and would certainly not have passed the censor of the Fatigue Board. The German titles are, with a few trifling exceptions, correctly rendered. The bulletin consists of a series of 168 readable abstracts and reviews classified under 14 headings, the longest section being diseases caused by bacteria and fungi, followed by protozoan and metazoan parasites, and filtrable viruses. A useful section summarises the many official reports which the veterinarian should know about. The editor of the bulletin is Mr. W. A. Pool, M.R.C.V.S., deputy director of the Bureau. The bulletin will be issued on the first day of April, July, October, and December, to subscribers at £1 for the volume or 7*s.* 6*d.* for a single copy. Application to the Imperial Bureau of Animal Health Veterinary Laboratory, Weybridge, Surrey.

MENTAL HOSPITALS IN AMERICA.

WITH the passing of the Mental Treatment Act, 1930, all "asylums" automatically became potential centres for the dissemination of mental hygiene and, no doubt, they will before long become mental hospitals in the truest sense of the word. The speed of their development along these lines must, however, depend upon the education of public opinion. Apart from these statutory institutions the hospitals which have been specially established for the early treatment of nervous and mental disorder and which enjoy the confidence of that large proportion of the population which still dreads the "taint" of "insanity" can be counted on the fingers of one hand. This is one of the things in which America has progressed beyond us. In its special hospital number for March the *Journal of the American Medical Association* publishes an analysis of hospital services in the United States; the figures show the astonishing result that the hospitals classed as "nervous" and "mental" far outnumber, numerically and in the number of their beds, hospitals of any other class except general. New York State alone has 59 mental hospitals; in the whole of the States there are 4302 general hospitals serving an average of 240,000 odd patients, and 561 nervous and mental hospitals serving an average of 415,000 patients. The next in the list are the tuberculosis hospitals, which number 515 and serve 56,000 patients. These figures prove conclusively that the American people are far more alive to the necessity for mental hygiene than we are. The article quoted indicates a demand for accommodation in mental hospitals comparable to our own, for 94·8 per cent. of the available beds are occupied, as against 64·7 per cent. of the beds in general hospitals. Government and non-Government hospitals have grown up together in many States. The Americans are making increasing use of their mental hospitals for teaching purposes; 31 out of 561 are affiliated with medical schools, and 63 offer 302 approved residencies in psychiatry. The report of our Board of Control for 1929 states that at the beginning of 1930 the number of persons under care for notified mental disease in England and Wales was 142,387; the proportion of persons under treatment to the population is therefore smaller in the United States than in England in the proportion of about 9 to 10, reckoning the population of the States as 130,000,000 and that of England and Wales as 40,000,000. These rates illustrate the crowded state of our mental hospitals which is constantly deplored by the superintendents. They claim that they cannot do their preventive and early mental treatment properly unless they have much more accommodation.

PHYSIQUE AND FEEBLE-MINDEDNESS.

THE existence of physical abnormalities in mentally defective people is familiar even to the layman, and much has been written about so-called stigmata of degeneration. Many early ideas on this subject were unscientific because the study of physical constitution was undeveloped. Recent work, however—especially the researches of Kretschmer and his pupils—has rendered possible a more accurate and refined investigation.

Dr. Eric Strauss, in a paper on the Psychobiological Constitution of the Weak-minded,[1] makes a well-balanced and stimulating contribution to a subject of importance not only to the doctor but also to the eugenist and the sociologist. His material consisted of 110 male defectives who superficially presented an appearance of physical normality. He thus excluded from consideration all the grosser types of psychophysical deficiency such as cretins and mongols, syphilitics and epileptics. He sought first to discover whether these 110 defectives could be grouped according to Kretschmer's classification of physical constitution in the three primary categories of leptosomatic, pyknic, and athletic. None exhibited the typical characteristics in an *uncontaminated form* and 11 were so dysplastic that they could not be classified at all. The remainder, though recognisable as belonging to one or other of Kretschmer's groups, exhibited various physical abnormalities of which genital dysplasias were the most frequent and striking. As might have been expected, there is little evidence that any single physical type predominates among mental defectives.

---

[1] Jour. Ment. Sci., 1930, lxxv.

Strauss's most interesting observations are concerned with the temperament of defective patients. As is well known, Kretschmer associates certain temperamental characteristics with his physical types. Strauss found, however, that this association was by no means constant among the defectives. In spite of the small number of pyknics among his 110 patients, the corresponding cyclothymic-cycloid temperament appeared in no less than 31 per cent. His explanation of this apparent discrepancy is based upon a theory of the evolution of temperament which deserves to be read in full. Briefly, he considers that the cycloid mental characteristics exhibited by the defectives represent a primitive temperamental type, an arrest in emotional development comparable to their physical and intellectual stunting. Dr. Strauss's paper also contains material bearing upon the frequency of the physical "stigmata" of mental defect, upon its heredity, and upon its association with criminality.

FRESH LIGHT ON JOHN ABERNETHY.

A MEETING of the Abernethian Society of St. Bartholomew's Hospital was held on April 20th to commemorate the centenary of the death of John Abernethy. Sir Arthur Keith, who was introduced by the President of the Society as a hero-worshipper of its founder, delivered an address with the title "Fresh Light on John Abernethy." "Just 100 years ago," he began, "my predecessor, William Clift, Conservator of the Museum of the Royal College of Surgeons, opened the 'Daily Remembrances' I hold in my hand, and entered under the date, Wednesday, April 20th, 1831, 'Mr. Abernethy died this day at half-past 5 P.M. at Enfield, Middlesex.'" On April 23rd "called upon Mr. Chantrey concerning Mr. Abernethy's death" and there follows a priced list of one pot of pomatum; plaister-of-Paris, a bag; two iron spoons; one small tool, and the record of a visit to Enfield. There Clift "was much gratified in being made certain that a cast had been made . . . when our friend was in the prime of life and includes the intire head and beginning of the neck." So are explained references to Abernethy in Clift's diary and particularly why Clift was so keen to secure from Chantrey a bust of his friend, and said Sir Arthur for himself, "it was while rummaging in Clift's diaries and being made to see Abernethy through Clift's eyes that the great surgeon of St. Bartholomew's became also a hero of mine." Telling much of the life-story of Abernethy, and of how Abernethy and Clift came together over the business of the Hunterian Museum, the lecturer reached the day when Abernethy felt compelled to retire from his seat on the college council. Before doing this he sent for Clift, and together they drafted the letter of resignation. The council decided to acknowledge Abernethy's merits in a suitable resolution, and Clift had much to do with its drafting. In its final form it contains a curious and puzzling phrase: "the contemplation of his bust must ever excite in liberal minds, emulative ideas of public virtue in the cultivation of useful knowledge." This written before a bust had been executed, explains Clift's hurried visit to Enfield after Abernethy's death. Sir Arthur Keith described Abernethy's house, Field Manor, Enfield, still standing, as it would have looked on the day of the funeral, and after touching on the revolution that has occurred in science during the last 100 years, closed with the following words: "We can never see Abernethy as his contemporaries saw him. The lesson that I would take out of that is—that what has happened to Abernethy's discoveries will happen to all of ours. Treat, then, our great dead with reverence. But there is one side of a man's nature which can never grow old—never pass out of date or fashion. That is his character. Abernethy as a man will never be out of date." A vote of thanks proposed by Sir Percival Hartley was seconded by Mr. W. R. Bett, who addressed the lecturer in the manner first of Sir James Paget and then of John Hunter. Lawrence's portrait of Abernethy, and Grove's bust had been placed in the lecture room, where also was an exhibition of Abernethiana arranged by Mr. J. M. Jackson, including Abernethy's gold repeater watch lent by the Royal College of Surgeons.

RELAPSING FEVER IN G.P.I.

AT a meeting of the Société de Thérapeutique of Paris Dr. Auguste Marie lately recorded his observations on 51 cases of general paralysis treated by inoculation of relapsing fever. The method, which had been suggested to him by Prof. Mesnil followed by Dr. Marchoux and Dr. Levaditi, was first employed in cases of general paralysis refractory to malariotherapy, in advanced stages where inoculation of the plasmodium was likely to be dangerous, and in cases where a rapid reaction was required. Inoculation of relapsing fever was also used as a method of prophylaxis against relapses in patients who had been inoculated by malaria and seemed to be immune to the plasmodium. The result of the treatment was that 18 of the 51 patients were discharged with a more or less complete and persistent remission; 16 showed an arrest of their physical symptoms but were detained in the asylum where some of them had been for several years; there were 17 deaths, 10 of which occurred within a few months after the treatment; and in the remaining cases there were remissions of varying duration. The average age of the patients who were discharged was 35 years, of those detained in hospital 40 years, and of the fatal cases 45 years. This suggests that with relapsing fever as with malaria the best results may be expected in young subjects. Some authorities think that relapsing fever is better tolerated by general paralytics than malaria, although there is not always a reaction. Hoche even maintains that the number of remissions is more frequent with relapsing fever. On the other hand, some observers who have tried both methods, such as Prof. Claude, still prefer the plasmodium of malaria to the spirillum of relapsing fever. Marie himself thinks that treatment by relapsing fever is a less reliable and more complicated method than malariotherapy, because after four to six passages from man to man the spirillum must be passed again through the mouse, whereas the plasmodium retains its virulence. In conclusion, he recommends that both methods should be supplemented by courses of arsenic or bismuth.

THE St. Cyres lecture for 1931 will be delivered by Sir Thomas Lewis at the National Hospital for Diseases of the Heart, Westmoreland-street, London, W., at 5 P.M., on Thursday, May 14th. His subject will be Ischæmia of Muscle as a Cause of Anginal Pain.

IT has been brought to our knowledge that half a gramme of radium element of guaranteed quality, set up in needles of various strengths, is in the market for disposal. Any request for further particulars will be passed on to the vendors.

---

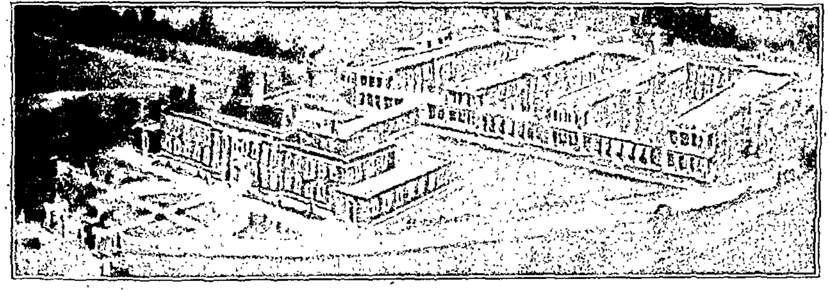
SPECIAL ARTICLES



King George Hospital as it will appear when completed.

KING GEORGE HOSPITAL, ILFORD.

It is an ironic comment upon much of the current talk about the coming "bankruptcy" of the voluntary hospital system that at the very moment when the primary responsibility for the provision of hospital services has been placed upon public authorities we are witnessing the rapid creation of a great new voluntary institution for the prevention and cure of disease. The building and equipment of a large general hospital is a very serious undertaking even when, as at Ilford, there is a nucleus to work upon, and it is easy to understand why the London County Council preferred to leave to voluntary effort the provision of so essential an accompaniment of their vast Becontree housing estate. One of its ex-chairmen, Sir George Hume, has given the enterprise his blessing; another ex-chairman, Sir Cecil Levita, has been its moving spirit.

King George Hospital has just completed its first year since the grant of a charter of incorporation, and the report of the board of management records a period of great activity and substantial progress not only in building but in increasing the volume and extending the scope of the work. The board has to cope with a demand which grows more rapidly than the means of answering it. As yet the accommodation is small, and a year ago it became necessary to plant out a part of the nursing staff to provide the additional beds for which the need was "desperate." The average of patients resident daily was thus increased from 55 to 67. Their average stay slightly exceeded 19 days and their weekly cost was £3 4s. 2d.

The original intention was to provide approximately 150 beds, but "the irresistible public demand" has compelled the board to move in advance of their means and to increase the number to 200. By making this extension while the builders are on the spot there has been a very large economy, the 50 additional beds costing no more than £240 each. This provident management ought to meet with its reward in the raising with comparative ease of the £25,000 which will still be required to enable the new hospital to be opened free of debt.

There could be no clearer proof of the need of hospital accommodation at Ilford than the fact that what is at present a small institution last year treated 131 more in-patients than in 1929, and that the number of out-patients rose from 2382 with 8427 attendances, to 4004 and 12,430 attendances. The Becontree centre, at Dagenham, an adequate modern building provided largely by the London County Council and local effort, is proportionately equally busy, and the usual public health services—school, antenatal, and infant welfare clinics, and a tuberculosis dispensary—have already been established. It is hoped that when the hospital is completed it will be opened by the King in person.

SWEEPSTAKES AND HOSPITAL POLICY IN IRELAND.

(FROM OUR DUBLIN CORRESPONDENT.)

It has been interesting to watch the changing attitude of the public in Ireland toward the policy of raising funds for hospitals by means of sweepstakes. When the plan was mooted first, the man-in-the-street thought that one or two such enterprises might succeed in freeing the hospitals from their more pressing difficulties, but not even the promoters dreamt of the huge sums that were about to roll in. The success of the November sweepstake startled the ordinary observer into interest, and the greater success of that held last month appears to him to indicate that untold wealth is at the call of those who gain sanction to promote a sweepstake for any object. The success of these two ventures has had its effect also on the minds of many governors of hospitals who had doubts a year ago about the wisdom of joining in what appeared to be a risky enterprise.

The vanishing of doubts has shown itself by the rapidly increasing number of hospitals participating in successive sweepstakes. Of the 13 major Dublin hospitals (ten general and three maternity) only three were concerned in the November sweepstake. Only five are standing out of the forthcoming ventures. Moreover, several provincial hospitals are now participants, and legislation is about to be introduced to the Dáil to legalise the county (rate-supported) hospitals to join in later sweepstakes. Again, all kinds of other ventures are asking for their claims too to be considered, that it may be made legal for them to raise funds by sweepstakes.

EFFECT ON ORDINARY SUBSCRIPTIONS.

It is not easy to say how far the governors of the hospitals which are still standing apart are influenced by questions of principle—or by mere considerations of expediency. There is no doubt that many individual governors feel strong disapproval of gambling. Some others, while disliking gambling, are questioning themselves as to whether they are right in putting their personal moral judgments as obstacles to the pecuniary benefit so easily attainable for their hospitals. A few subscribers, who disapprove of gambling, have transferred their support from the participating to the non-participating hospitals, as has also the Dublin Hospital Sunday Fund. On the other hand, many who occasionally subscribed to the hospitals as charities, but were not particularly interested in the work, are fastening up their purses in the comfortable belief that the participating hospitals no longer need their help, and that the non-participating hospitals could become equally independent, if they were willing to divest themselves of foolish scruples. In the result, none of the hospitals—participating or non-participating—is in a position to judge where it stands as regards its future income from the charitable public.

DOUBTS.

Nevertheless, although the man-in-the-street is content with the obvious fact that the hospitals are getting money easily, there are many more thoughtful observers who regard the method as unsound, morally or economically or both, and do not look with equanimity on the prospect of the burden of the care of the sick poor of Ireland becoming a charge on the gambling spirit of the world. In particular, it is urged in many quarters that the proposal now before the Dáil to permit certain rate-supported institutions to share in the benefit of the sweepstakes is humiliating and improper. If the natural responsibility of the rate-payer as regards public hospitals is transferred to the gambler in China or Peru, then it becomes difficult to know where to draw the line. Why not put the whole maintenance of the hospitals on the sweepstakes? Or the charge of the salaries of medical officers of health? Or the upkeep of the roads? Why not go further, and support the Government of the country itself on sweepstakes, as certain of the minor princes on the continent draw their incomes from their gaming tables?

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

THE FOUNDATIONS.

IN a country where even the most limited proposals for federal aid to health work arouse active opposition—especially from the medical profession—the work of the endowed foundations in promoting and forwarding public health research and administration becomes of really national significance. Reports of four of the leading funds [1] are recently to hand. The *Milbank Fund* announces the termination of the three health demonstrations in New York State. These demonstrations have now been in progress for eight years and may be considered to have fulfilled their purpose of demonstrating in a rural, a town, and a metropolitan area respectively something of the possibilities of an intensive public health campaign. The results achieved in the rural demonstration in Cattaraugus County are reviewed in a book (now in press) by Prof. C. E. A. Winslow.[2] Dr. Winslow agrees that the county demonstration, like other human enterprises, failed to achieve perfection, but says that "it was conceived with remarkable soundness and in the main executed with efficiency and economy" and "represents one of the most effective and inspiring contributions made to the cause of rural public health anywhere in the world." He finds that as a result of the eight years' public health work the county is saving 20 infant lives, 5 lives from diphtheria, and 14 lives a year from tuberculosis. In these three classes alone he estimates the gain to the community at $300,000 a year. It is evident that the County Board of Supervisors have also been convinced that health work pays, for despite the general financial retrenchment they have increased their appropriations for public health from $66,000 in 1930 to $87,000 in 1931.

A similar critical review of the demonstration in the city of Syracuse is contemplated. It is roughly to be measured by the achievement of a low infant mortality-rate. This reached a minimum of 55·7 in 1929. The estimated rate for 1930 is approximately the same. The municipality, which appropriated $144,000 for public health in 1923 (the first year of the demonstration) appropriated $314,000 for the same purpose in 1930.

References have already been made in these letters to the work of the Bellevue-Yorkville health demonstration in the metropolis. The immunisation of over 200,000 city children against diphtheria is not the least among its accomplishments.

The *Rosenwald Fund*, founded in 1917 "for the well-being of mankind," has been expended mainly for educational and health work among the negroes. The fund is coöperating with the U.S. Public Health Service and State authorities in five experiments in the control of syphilis. Aid has been given in placing 31 coloured nurses in southern county health units. Hospitals and institutions for coloured people have also benefited, including a negro birth-control clinic in New York City. "In all these activities in behalf of negro health a most important feature is coöperation between white and coloured groups in financial support, management, and medical direction. In so complex a subject as medicine" writes Mr. Embree, the president, "negroes must for many years lean heavily on the superior training and longer experience of their white colleagues."

The *Rockefeller Foundation* specialises in giving assistance to official health agencies both in this country and abroad, and also in the encouragement of promising research workers by the giving of special grants and of fellowships. During the last year governments in various parts of the world have received aid for purposes of public health education, for the strengthening of central and local health services, and in the scientific study of their public health problems. During 1930, 52 articles in the medical press reported work done by members of the field staff or persons working under the auspices of the Foundation. Work on hookworm disease is in progress in 14 different countries, on malaria in 15 countries as well as in the United States. Research on yellow fever is still a major interest of the Foundation. It cost the life of one of the younger and most promising of research workers, Dr. Theodore B. Hayne, who died at Lagos, Nigeria, on July 11th, 1930.

[2] Health on the Farm and in the Village. By C. E. A. Winslow, professor of public health, Yale Univ. School of Medicine. New York: The Macmillan Co. Pp. 275. $1.

The *Commonwealth Fund* has three broad interests: Public Health, Mental Hygiene, and Anglo-American relations. The public health work done with its aid is somewhat like that carried through by the Milbank Foundation. However, it has concentrated more upon the education in public health of the medical profession and has been spread over a larger territory. In each of the States in which the Commonwealth Fund is assisting to develop public health service "to the point of greatest usefulness within the limits of sound budgeting," 15 scholarships are provided annually for rural physicians who will receive post-graduate instruction not only in public health but also in the various fields of medical practice. Scholarships for post-graduate nursing study are also provided.

During the academic year 1929–1930 60 English fellows were in residence in American universities. During the present academic year the number is 68. Very interesting reports are furnished by these fellows of their experiences in America. The summer travel which intervenes between the two years of university life is rightly emphasised as an important feature of the plan.

In mental hygiene the fund has been active in the promotion of child guidance clinics and in securing for them the right kind of trained personnel. Their assistance in developing the child guidance clinic in London has doubtless made this phase of their work familiar to English readers. The new London house of the Commonwealth Fund is at 35, Portman-square.

PUBLIC HEALTH SERVICES

REPORTS OF SCHOOL MEDICAL OFFICERS.

—	No. on roll.	Average attendance.	Routine inspections.	Special exams. and reinspections.	Percentage of defects.
Sheffield . . .	76,949	70,224	19,128	138,882	16·76
Eccles	—*	—*	1,978	3,189	21·28

* Not stated.

Sheffield.

Dr. T. Chetwood says that the record of the past year shows continual improvement in the health of the school-child in the city. It must not be forgotten, however, that the real object of the service must be prevention of disease rather than its cure. Of the children under 5, only those few who attend the nursery schools have the benefit of the school medical service, and it is apparent, he adds, that many of the problems that face the school medical officer originate among the children of pre-school age. The expansion of the service is illustrated by the increase of nearly 30,000 in clinic attendances, mainly due to the extension of the dental facilities and to a rapidly growing number of minor surgical dressings, of which both parents and teachers are eager to avail themselves. Routine dental inspection is now carried out in 122 out of 137 schools This has been rendered possible by augmentation of the dental staff which now numbers eight dental surgeons with the necessary assistants (this gives one dentist to about 9500 school-children), and a new branch clinic opened at Heeley last May. A special feature in Sheffield is the extension of facilities for children actually suffering from toothache and the large use made of them. This scheme is seemingly in contrast with the policy of some other large towns, such as Hull, where casual treatments are being eliminated and attention concentrated on prophylactic work. Dr. Chetwood notes that the percentage of parents accepting treatment for their children was five more than last year; the present figure of 58 per cent., he says, is better than in some other large areas. An activity more nearly preventive in character is the rheumatism scheme which is to be considered in Sheffield at an early date. An outstanding event of the year was the opening of the new open-air school at Bents Green with 50 resident children and 100 day scholars. Children are transferred from the residential to the day school; the improvement in health is shown especially in a higher standard of nutrition, of skin condition, and of cleanliness. The proportion of children in nursery schools may as yet be small, 270 places for 98,447 children of school age, but the results are such as to encourage the hope of rapid extension. This report lacks the accounts of special investigations which were formerly such an interesting feature of Dr. Chetwood's record.

Eccles.

Dr. J. E. Spence directs his glance over the child's whole school life and backwards to its need for care before coming to school. The close coördination of the infant welfare and school medical work has been maintained, and continuous supervision exercised from birth up to the school-leaving age; the two services are in fact unified in Dr. Spence himself. There are no nursery schools in the borough, but 586 children between the ages of 3 and 5 were in attendance at elementary schools. All the facilities of the school clinics are available for infants and toddlers; during the year there were referred from the infant welfare centre 45 cases of minor ailments, 20 for squint and defective vision, and 37 for toothache. A special inspection was made by Mr. Harry Broughton, L.D.S., of 119 children aged 5, to ascertain what advantage, if any, was to be gained by earlier routine treatment—i.e., beginning at 5 instead of 6. Of this sample 63 per cent. were found to need treatment, and the support of the parents was satisfactory. At the age of 5 the treatment needed is not generally extensive, and the advantages of improved general health and freedom from pain and disturbance are great. Earlier inspection would no doubt facilitate the orthodontic work on which Mr. Broughton spends much care. Orthopædic treatment is being developed in a scheme by which children are dealt with at the Irlam clinic of the Lancashire County Council, to which they are conveyed, if necessary by ambulance, in charge of one of the school nurses. They are there seen by Mr. E. S. Brentnall, under whose supervision remedial treatment is carried out, those requiring prolonged hospital treatment being sent to the orthopædic hospital at Biddulph; minor operations are done at Ancoats Hospital. Out of 30 children taken to the clinic, 9 were under school age. A frequent source of deformities is infantile rickets which might have been avoided if the parents had made better use of the welfare centres, but it is difficult to convince parents of the need for early treatment when their other children had bow legs and "grew out of them." A similar attitude is equally a hindrance in the case of impaired vision and stammering. It seems strange that in a time of depression like the present, when employment is difficult to obtain for the normal child, parents fail to realise what a poor chance there is for those with a disability. There is in Eccles a stammering class which does excellent work and could do more with parental coöperation. Dr. Spence wishes that the children themselves should realise their handicaps and so be led to get quit of them, but most teachers are anxious of the sense of inferiority felt by the child who dwells on his own disability.

Soke of Peterborough.

Dr. Christopher Rolleston mentions the experiment of inviting parents to bring their younger children, who in other areas would be dealt with at infant welfare centres, to be examined at the school inspections. The plan was good but, unfortunately, the response was small. Good progress has been made with the scheme for dealing with tonsils and adenoids, 38 children in the last twelvemonth, compared with 12 in the previous. Five were operated on privately, making a total of 43 receiving treatment out of 101 needing it, a proportion smaller than that for the country as a whole, which is 55 per cent. It should be noted, however, that the percentage of children considered to need treatment in the Soke is high—10·5 compared with 6·6 for England and Wales; thus it is probable that quite as large a proportion of the obvious cases were dealt with in this area as elsewhere. Dr. Rolleston gives his reasons for attaching importance to the presence of tonsils and adenoids: deafness and earache were common; in 70 per cent. definite changes were seen in the drum of the ear; malnutrition, rheumatism, and pigeon-chest were found, and, above all, mental retardation. In dental work again there is evidence of a high standard of ascertainment: every child in the Soke was inspected and 80 per cent. were found to need treatment, compared with only 56 per cent. inspected and 68 per cent. of them deemed to need treatment in the country as a whole. But in the Liberty of Peterborough the percentage of acceptances was low: 45 against 59. Both with adenoids and with dental decay Dr. Rolleston thinks the failure to accept the facilities is mainly due to the children; "the modern child," he writes, "rules its parents with a rod of iron, and if the coöperation of these juvenile tyrants could be secured, the statistics would be enormously improved." Dealing with results, he observes: "If, however, dental inspection and treatment are carried out annually, the parents can be told that the children, when they leave school, will have sound teeth, but, unfortunately, when they leave they do not enter upon the National Health Insurance scheme for another two years, and it is another two or three years before they are entitled to dental benefit, so that a large proportion of the good work of the school dental service is undone." Of the teaching of hygiene, he paints a gloomy picture: "Generally speaking, no definite time is assigned to this teaching, nor are the children held to share in the responsibility for the care of ventilation and cleanliness of class-rooms and the proper conditions of lavatories and playgrounds. What are the results of this neglect? In the first place the children do not appreciate that disease and even death are conveyed by uncleanly habits. . . . From all this neglect come outbreaks of infectious disease and much chronic ill-health, while the provisions for medical and dental treatment are not appreciated." Here as elsewhere in the report Dr. Rolleston's frankness is devoid of offence, for his concluding words contain an expression of thanks to teachers for the interest they show in the physical well-being of their scholars.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 11TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 177; scarlet fever, 1480; diphtheria, 844; enteric fever, 35; pneumonia, 1410; puerperal fever, 48; puerperal pyrexia, 109; cerebro-spinal fever, 73; acute poliomyelitis, 1; acute polio-encephalitis, 1; encephalitis lethargica, 16; dysentery, 2; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 14th–15th was as follows: Small-pox, 100 under treatment, 7 under observation (last week 221 and 5 respectively); scarlet fever, 1223; diphtheria, 1602; enteric fever, 36; measles, 136; whooping-cough, 454; puerperal fever, 27 (plus 14 babies); encephalitis lethargica, 129; poliomyelitis, 2; "other diseases," 18. At St. Margaret's Hospital there were 17 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was one death from small-pox, none from enteric fever, 64 (1) from measles, 8 (3) from scarlet fever, 39 (7) from whooping-cough, 27 (9) from diphtheria, 40 (8) from diarrhœa and enteritis under two years, and 175 (20) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to Stepney (metropolitan borough). Only 4 deaths from meningococcal meningitis occurred in London, 1 from 1–2 years, 2 from 25–35 years, and 1 from 35–45 years. Seventeen fatal cases of measles were reported from Liverpool, 16 from Birmingham. Manchester reported 5 deaths from whooping-cough, Sheffield 3. Diphtheria claimed 4 victims at Liverpool. Diarrhœa accounted for 5 deaths at Liverpool and 4 deaths each at Stoke-on-Trent, Birmingham, and Salford. The 155 fatal cases of influenza outside London are scattered over 60 great towns: 15 were reported from Birmingham, 8 from Sheffield, no more than 6 from any other large town.

The number of stillbirths notified during the week was 318 (corresponding to a rate of 47 per 1000 births), including 60 in London.

DEATH CLASSIFIED TO SMALL-POX.

The death mentioned above, provisionally classified to small-pox, was that of a female infant, aged 7 days, which occurred on April 1st, the cause of death being certified as "inanition, small-pox in utero." Dr. Julia M. Browne, medical officer of health for Stepney, informs us that the infant's mother was removed to hospital with small-pox on Dec. 13th last and was discharged on Jan. 7th. The child was born on March 25th almost moribund—a small, poorly developed baby, with a sodden, unhealthy looking skin. There were one or two marks on the chin and elsewhere which could by reason of their character be reasonably attributed to small-pox occurring in utero. Dr. Browne adds: "It seems to me that the mother contracting small-pox three months before the birth of the child precludes the possibility of small-pox in utero being the immediate cause of the death of the child."

CONTRIBUTORY SCHEME FOR ADDENBROOKE'S HOSPITAL.—The governors of Addenbrooke's Hospital, Cambridge, last week adopted a contributory scheme prepared by the general committee of the hospital and the committee of the Cambridge and district workers' hospital fund. The scheme is divided into two sections. One covers the borough of Cambridge and will be administered by the workers' fund; the other will cover the whole of the rest of the area served by the hospital and will be administered by the governors. There will be a maintenance charge for both classes of non-contributing patients, letters of recommendation will no longer be necessary, and a paid almoner is to be employed. It is expected that the scheme will be in working order by October next.

REOPENING OF TENBURY HOSPITAL.—The decision, which was arrived at in November, 1929, to close Tenbury (Worcestershire) cottage hospital and sell the building and equipment has now been rescinded. Meetings to ascertain local opinion had a very favourable result, and it is estimated that a contributory fund of £800 will be available, and the help from other sources will bring the total income to about £1200 which it is thought will suffice to maintain all the activities of the institution. It is proposed to provide a medical service to include the treatment of patients in their own homes by district nurses, treatment at Tenbury Hospital, and, where necessary, at Worcester, Kidderminster, and other large hospitals.

CORRESPONDENCE

THE POST-GRADUATE HOSPITAL AND SCHOOL.

To the Editor of THE LANCET.

SIR,—The advent of a satisfactory centre for post-graduate medical education in London has advanced a stage further. Even if all cannot entirely share the optimism of the Minister for Health which prompted him to describe the institution of the post-graduate hospital and school as "perhaps the biggest single step taken since the war in this country in the interest of public health"[1] yet we may certainly believe that the conclusion of the preliminary labours of the organising committee and its entry on the task of setting up a governing body of the hospital do really foreshadow a centre for post-graduate education on a large scale, such as many, including THE LANCET, have for years worked and pleaded for. Mr. Greenwood's hopes can be shared even if we are a little shy of his sanguine expectations, for there are difficulties which may beset and obstacles which may oppose that consummation which the Minister of Health and the medical profession in common hope to witness.

Why has post-graduate education in London hitherto been but a partial success and why should it be more satisfactory in the future? In order to answer these questions convincingly we must first decide at what exactly this education will aim, or to put it more correctly what kind of post-graduate students do we hope and expect to attract? If, as some who have written on this subject appear to believe, the authorities hope and expect to compete with Vienna and Paris and Berlin in attracting medical men from all over the world, then, I am sure, many will agree with me and regard such expectations as ill-founded. There is at least one overwhelming reason which makes it impossible for London to compete with continental capitals in a worldwide appeal to post-graduates. What the post-graduate values above all is the opportunity to do for himself those things which he has not yet had the chance of doing. It is not enough that he should listen to lectures on, or even witness demonstrations of, the new methods of diagnosis and of treatment of which he has probably already read. It is the actual carrying out of these manœuvres, after due instruction, which is the most valuable contribution that post-graduate courses can offer him. Now this is where the continental method has an insuperable advantage over the British. In the clinics of Vienna, for example, patients are available for the eager, if unpractised, hands of the post-graduate learner to an extent which our notions of what is due to the patient's feelings and well-being render impossible here. Therefore the British post-graduate school cannot offer the facilities, let us say, for learning to use an endoscope or for carrying out gynæcological examinations or minor operations, that are put at the post-graduate's disposal in almost infinite quantity by the great clinics abroad. Hospital departments, with us, exist primarily for the benefit of the patients, but post-graduate centres abroad exist primarily for the benefit of the students. This British disability, admirable though its cause, is bound to prevent our post-graduate school from entering into exact rivalry with the great European centres by attracting foreigners, or even our own men from overseas.

As far as success for our post-graduate school rests on the support of our own doctors the answer depends on the quality of the opportunities offered, and here, no doubt, in buildings, equipment, clinical material, and the personnel of the teaching staff, the new hospital and school will provide all that the most exacting could demand. The Government are obviously generously disposed so far as financial endowment is concerned. Why, then, doubt for a moment the extent to which medical men in these islands will avail themselves of a fine opportunity for refurbishing from time to time their knowledge and skill? The answer lies, of course, in the exigencies of the practice of medicine. It is no easy matter for the practitioner, especially if practising single-handed, to leave his practice to undergo a course of post-graduate instruction; many find it none too easy to make the annual break which considerations of health and of family render almost imperative. For those who have partners the difficulty is, of course, much lessened. Unfortunately, it is the man who practises single-handed who may feel most keenly the need of either "refreshing" or new special instruction.

It is a splendid thing that a great post-graduate centre is to commence its activities in the metropolis, but its institution brings difficulties alike in the selection of the staff and the recruiting of the students, other than those who belong to services where facilities for study leave are provided.

I am, Sir, yours faithfully,

SIMPLICITAS.

April 20th, 1931.

UNDULANT FEVER IN SHIPS.

To the Editor of THE LANCET.

SIR,—I would like to thank Fleet-Surgeon Home for drawing my attention to the mysterious epidemic of fever in H.M.S. *Thalia* which had escaped my notice when searching the naval records of 1883. This epidemic is better evidence than any I gave in the Milroy lectures, that brucella infection in ships was often transmitted directly from man to man and not by milk. The *Thalia* was carrying out relief crews to ships in China; she obviously embarked *Br. melitensis* when she touched at Malta. Undulant fever continued to spread in the *Thalia* till she arrived at Hong-Kong, and in the ships of the China squadron, to which she transferred her drafts. Listen to this description of "*Thalia* fever": "The temperature generally remained high up to the fourteenth day when it commenced to fall sometimes to normal . . . . after a period of normal temperature a relapse occurred without any indication, and so on for three or four attacks over a period of several months." In addition there is the absence of mortality, the rheumatic sequelæ, and "the tongue coated with a thick white fur, tip and edges red." Is it possible to apply this description to any other condition than undulant fever? Fleet-Surgeon Home says, "Surely this fever was due to want of ventilation, and not brucella septicæmia." If the negative is omitted, I agree with him. It was the gross overcrowding and bad ventilation of the transport which permitted the direct transmission of *Br. melitensis* from man to man.

I am, Sir, yours faithfully,

SHELDON F. DUDLEY.

Royal Naval College, Greenwich, April 18th, 1931.

---

[1] The Times, April 15th.

OUT-PATIENT DEPARTMENTS AT VOLUNTARY HOSPITALS.

To the Editor of THE LANCET.

SIR,—In your leading article of March 14th you begin with the sentence: "The least satisfactory feature about our hospitals is the out-patient departments." The same dissatisfaction is revealed in certain suggestions concerning out-patient departments at voluntary hospitals brought forward by the Council of the British Medical Association in the Supplement to the *British Medical Journal* of Feb. 21st. As is, of course, well known the Council of the Association brought forward last year another scheme which envisaged the extension of the National Health Insurance Act to the dependents of insured persons, and the present suggestions are supplementary to that scheme, which, if adopted, would bring probably seven-eighths of the whole population of this country under the operation of the Insurance Acts.

The out-patient departments of the voluntary hospitals have become something of an eyesore to those who are anxious to consolidate all the public medical services as far as possible in the hands of the practitioners who work the Insurance Acts. Pari passu with this movement, of which the Council of the British Medical Association is the spearhead, there is another movement which seeks to nationalise the whole medical profession and to transfer entirely to State control all the medical services, including both the panel and the hospitals. The latter movement, which has the whole-hearted support of the Labour party, and which indeed forms one of the planks of their programme as detailed in "Labour and the Nation," has received a very remarkable stimulus from the propositions put forward last year by the Council of the British Medical Association. In a leaflet recently published by those who are promoting a nationalised medical service the proposals of the Council of the British Medical Association as regards extension to dependents are welcomed as a very important advance in the direction of nationalisation. These promoters say, in fact: "We consider that the scheme, with modifications, could be made a forward step towards a free public universal medical service," which is the ideal aimed at by the Labour party. I do not now propose to consider the suggestions of the Council of the Association regarding the inclusion of dependents, but to deal more particularly with their latest proposals regarding out-patient departments at voluntary hospitals.

The British Medical Association, which by its constitution and traditional policy is mainly concerned with the defence of the interests of the panel practitioner, is disturbed by the growth of out-patient departments, and these suggestions are made to counteract that growth, which indeed shows a progressive and, perhaps, unexpected increase. One would have thought that the establishment of national health insurance, with its compulsory contributory clauses, bringing very large numbers of the working population under its operation, would have depleted the out-patient departments at the voluntary hospitals, and this expected result actually occurred in the years immediately succeeding the passage of the Act; from 1911 to 1920 the numbers of out-patients materially diminished. Statistics demonstrate that from 1920 onwards the figures of out-patient departments have risen each year until now they exceed the figure for the year 1911, when the Insurance Act first made its appearance. In the latest report available, published in 1929, in 661 hospitals in England and Wales, excluding London, the number of out-patients is given as 2,589,312, as against 2,136,770 for 657 hospitals in the same area in 1921. A similar growth is recorded for the London hospitals; in 1921 there were 1,451,533 new patients at the out-patient departments, as against 1,760,807 in 1929. The reasons for this growth are difficult to assess and are probably very complex and diverse. I do not think it can be gainsaid that the control by the State of insurance practitioners has steadily increased with the years since the Act came into operation in 1912. With the extension of State control the service of the Acts has undergone some modification, and there is an increasing interference with the liberty of the practitioner by Government departments. Partly, perhaps, as a result of that interference there are widespread indications that insured persons themselves are increasingly dissatisfied with some of the circumstances of national health insurance and I submit that this change of feeling would go far to explain the increased popularity of the out-patient departments at the voluntary hospitals; those who are in charge of departments at the hospitals must have been impressed by the frequency with which patients coming to out-patients declare that they come because they are dissatisfied with the service which they have received under the panel.

With the present system of contributions by out-patients the visit means a direct expenditure by the patient that in itself argües a certain discontent with the panel service for which he has to make a contribution, but which he does not use. The English race is probably the most individualistic in the world, and those who imagine that they can force English men and women to accept a medical service which they dislike are singularly oblivious of the national character. One can take a horse to the water but one cannot make him drink.

Let us now examine the suggestions which the Council of the British Medical Association puts forward to divert the hospital out-patient from the hospital to the panel practitioner. In the memorandum just issued the thesis is laid down that the primary object of the out-patients department should be for consultation, and the following clauses contain the gist of the proposals:—

> "That while there should be adequate opportunities for consultation purposes between the private practitioner and members of the visiting medical staffs at out-patient departments, practitioners should not countenance the use of that department by their patients, except in the ways laid down in this memorandum.
>
> "That no person, except in cases of emergency, should be accepted for treatment as an out-patient at a voluntary hospital unless he brings a recommendation from a private medical practitioner, a provident or other dispensary, a public clinic, or from a public assistance medical officer of a local authority."

As a corollary of these propositions it would seem to be required that every new patient coming to a hospital without bringing a letter should be referred back to his own doctor, and that treatment should only be given when the sanction of the doctor has been obtained. Hospitals are not to receive patients unless "countenanced" by the panel practitioner, acting under the orders of the Council of the British Medical Association. The large and increasing class of patients who are dissatisfied with the conditions of panel practice and would not ask for letters from their doctors would thus be refused both consultation and treatment, and inasmuch as the opportunity which the out-patient departments afford to persons who think they have been inadequately treated, and who may in fact have been inadequately treated, would thus be abolished, to the great detriment, I submit, of the insured population, hospitals enforcing these regulations would be in immediate conflict with a large body of public opinion. Even if the medical profession wished thus to convert itself into a trades-union, which I question, would it be strong enough to force such a position on the community, and would not such a step be the surest way of playing into the hands of those who so ardently desire the nationalisation of all the medical services?

I believe (and I am sure that my belief is shared by many) that if it had not been for the resources provided by the voluntary hospitals the national health insurance service would have long since foundered, and it seems to me to be singularly short-sighted for those who desire the retention and even extension of that service to take the action which they are now proposing in the direction of restraining by artificial regulations the resort by panel patients to hospitals.

I do not think that members of hospital staffs have given any serious thought to these matters, and I think it is high time that they should do so. At this crisis when the voluntary hospitals are being subjected to a competition from State-aided institutions enjoying, for the moment at any rate, the hectic prosperity engendered by an unprecedented squander-mania that seem to have infected all local public authorities, the abrogation of unrestricted access to these hospitals, which the community shows an increasing desire to obtain, seems to me to be a disastrous step to take, and one entirely opposed to the best traditions of the voluntary hospitals themselves. The strength, and it is a very enormous asset, of the voluntary hospital system lies in the fact that voluntary service consorts with the temperament and tradition of the English race. Its weakness, and it is a deplorable weakness, is that action is too often isolated when it should be concerted. Unfortunately there is no efficient official organisation to ensure such concerted action. There is, however, one body to which, in my submission, the *London* voluntary hospitals, at any rate, could make a common application for advice and guidance, a body which enjoys an increasing prestige with the subscribing public and with the hospitals themselves—namely, King Edward's Hospital Fund—which has been able to secure the wise simplification and uniformity in presentation of hospital accounts which now prevails; before accepting any departure of policy so radical as the imposition upon the voluntary hospitals of a purely consultative service as desired by the Council of the British Medical Association, I venture to suggest that the hospitals should consider the whole problem jointly with each other and in consultation with the authorities of that Fund. I am, Sir, yours faithfully,

E. GRAHAM-LITTLE.

House of Commons, April 21st, 1931.

SYPHILIS AND YAWS.

To the Editor of THE LANCET.

> Truth crushed to earth shall rise again:
> Th' eternal years of God are hers;
> But Error, wounded, writhes in pain,
> And dies among his worshippers.
> (*Bryant.*—The Battle Field, St. 9.)

SIR,—The first two lines of the above stanza are doubtless true. William Cullen Bryant was wrong, however, in the two last lines of this verse because error crushed to earth will do the same thing as the poet found truth would do: it will rise again. Some medical errors seem not to do much "writhing" among their worshippers either. Many are hoary with age and yet physicians are perpetuating them to-day in both popular and professional literature. In other words, physicians are the chief worshippers of these errors.

The Ancient European ancestry of syphilis may be shown in a dozen ways, direct and indirect, and yet we find in current literature physicians subscribing to the moth-eaten fallacy that syphilis is of New World origin. So, too, with the yaws fallacy. Since the time of Sydenham and long before him, there have been English and Continental physicians who "thought and taught" correctly about framboesia. Berkeley Hill of English and E. Lancereaux of French physicians, both of the third quarter of the nineteenth century, have shown how completely the yaws syndrome is identified with syphilis. The researches of these older writers have been backed up by clinical, epidemiological, and laboratory researches without number. On the other hand, research workers during the past forty years trying to prove the theory of duality of viruses have failed, so that to-day it is possible to say that yaws is purely an artefact erected over the disease syphilis. This statement is made with the hope that some dualist will produce evidence to the contrary. There has been ample time for all such evidence to assert itself.

The yaws fallacy has persisted in medical literature for two hundred years almost and is so far advanced that practically all English, Continental, and American text-books on tropical medicine give it extensive description. This is due largely to the "library case" made out for yaws and to the repetition from volume to volume and edition to edition of the ever-growing fallacy, thus completing the vicious circle between teacher to student. Recalling the fate of Socrates in similar case, we may well feel that some fallacies of the "Guild of Æsculapius" are virtually immortal and that truth when crushed to earth often takes centuries "to rise again."

I am, Sir, yours faithfully,

C. S. BUTLER,
Captain (M.C.), U.S. Navy.

Washington, D.C., April 8th, 1931.

THE ST. LUKE'S HOSPITAL, HEBRON.

To the Editor of THE LANCET.

SIR,—Is there any medical man among your readers, or known to any of your readers, who would consider an invitation to take charge of St. Luke's Hospital, Hebron, in Palestine? This is a mission hospital, which is financed by the Jerusalem and the East Mission, and is the only hospital in this large Moslem town of 16,000 people. There is no other hospital within 20 miles, and there are many villages in the district which have no other place to turn to for treatment. The experience of the last 18 months has shown that in fact village patients come in considerable numbers from a very wide area, sometimes walking two or three days to reach the hospital.

Medical missionary work has been carried on in Hebron for 38 years, before the war by the United Free Church of Scotland, and since the war by the Church of England. The actual hospital building is new and has been brought up to date, with its own electric light plant, &c., during the last few months at an expenditure of some £3500. There is an English sister as matron and a competent native doctor and staff. The whole usefulness of the hospital is at present seriously limited by the lack of an English doctor. From the professional point of view the work would be most interesting, and it is essential that whoever offers should be a surgeon. There is no other missionary work at present possible in the town or neighbourhood, so that the opportunities before the hospital cannot be exaggerated. There is a chapel in the hospital building, and the grounds are large enough to permit of building a house for the doctor if suitable rented accommodation is not found. From the date that it was reopened, in September, 1929, just after the serious riots, the work of the hospital has received a great welcome from the people of the town, while relations with British government officials have been most cordial.

If any of your readers desire further particulars would they communicate with my Commissary, the Rev. E. M. Bickersteth, Secretary of the Jerusalem and the East Mission, 12 Warwick-square, London, S.W.

I am, Sir, yours faithfully,

RENNIE MACINNES,

St. George's Close, Jerusalem, April 11th, 1931. Bishop.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

MINISTRY OF HEALTH VOTE.

CRITICISM OF GOVERNMENT'S RECORD.

ON April 14th the House of Commons discussed in Committee of Supply a vote of £13,116,212 for the salaries and expenses of the Ministry of Health.

The speech of Mr. GREENWOOD (Minister of Health) in introducing the vote was reported in THE LANCET last week.

SICKNESS AND DISABLEMENT BENEFIT.

Sir KINGSLEY WOOD said he was glad to hear what the Minister had said about National Health Insurance claims, because they were giving considerable anxiety to many of the approved societies. He observed that only a week or two ago the Controller of National Health Insurance, when addressing an important insurance conference, stated it was still necessary for certain societies to strengthen the safeguards adopted by them in connexion with the supervision of claims. He (Sir K. Wood) was glad to know that within the last few months the Minister of Health, without being accused of treating unfairly and improperly the insured classes of the country, had altered, for instance, the regulation affecting change of doctor by insured persons, and that in other ways he was endeavouring to tighten up administration. With regard to the Local Government Act, they were told in 1928 by Mr. Greenwood that that Act perpetuated the evils of the poor-law system, made no provision for the prevention of destitution, and was calculated to increase the high mortality rates among mothers. Only a fortnight ago, however, the right hon. gentleman was saying how smoothly the enormously complicated transfer of functions under the Act had been carried through. He had also said that the transfer merited high praise for all those concerned in it. With regard to the question of housing, Sir K. Wood said that after two years of a Socialist Government more than 200,000 building operatives were walking the streets unemployed; a large number of people had failed to obtain the housing accommodation which they were promised; the output in municipal building had been reduced, and but for the contribution of the private capitalistic builder, there would not have been built even sufficient houses to meet the ordinary growth of the population, and to replace wastage.

MATERNAL MORTALITY.

Viscountess ASTOR said there was a way out of the slum problem, and that was the provision of open-air nursery schools. The Minister of Health had said he was pleased with the health of the country, but in 1929 88,524 children died under the age of 15; and of these 74,497 were under the age of 5. Infant mortality had gone down, and the great loss of life really occurred between the ages of 2 and 5. The House might have expected that the Minister of Health would have some plan for dealing with the situation. She hoped the Government would face up to the problem before it was too late. The Minister of Health was pledged up to the hilt to deal nationally with the question of maternal mortality, but he had not said one word about it in his speech. That was disappointing and disheartening.

HEALTH INSURANCE.

Dr. MORRIS-JONES said he was very disappointed with Mr. Greenwood's speech. The Ministry of Health touched intimately the lives of the people. He had hoped that the right hon. gentleman would have made some reference to future legislation dealing with national health insurance. He was very pleased to hear that the cost of sickness and disablement benefit was reduced last year by £2,000,000. That was a testimony to the very efficient public health services of the country, which were the best in the world. National epidemics of diseases, such as influenza, had been proved to be capable of prevention to a very large extent. He was pleased to find in the report of Sir George Newman for last year that influenza was much less both in extent and virulence than in the preceding year. A great advance had been made in the treatment of this very serious type of illness, the consequences of which were immeasurable in their effect on the physique of the population. He was disappointed that Mr. Greenwood had not promised that the report of the Inter Departmental Committee on the alleged excessive claims for national health insurance sickness benefit would be published. They wanted to know the real causes of these excessive claims. If the report had been published the House would probably have been able to appreciate more clearly the recent departmental Order issued by the Minister of Health in regard to change of doctor by insured persons. That Order, which greatly curtailed the opportunities of the insured population to change their medical attendants, was issued contrary to the wishes of those who spoke for the medical profession. Their point of view was that it was not altogether in the interests of the insured person, and it was not in the interests of the efficiency of medical treatment to curb or limit drastically the opportunity of a patient to change his doctor.

POST-GRADUATE MEDICAL SCHEME.

The House had been much interested by the remarks of Mr. Greenwood with regard to the post-graduate medical school which was initiated by his predecessor, and had been followed up by the present Government. The advances in medical science in recent years had been tremendous, so much so that those medical men who had received their training 20 or 25 years years ago found the greatest difficulty in keeping up with the great and rapid changes in the prevention, diagnosis and treatment of disease. A hard-working general practitioner who worked day and night had very few facilities and inadequate leisure to enable him to study and to keep up to date in medical science. It was often said that specialists were the great people, but in his view the general medical practitioner was the first line of defence against disease. He came into contact day by day with the people, and it was of the greatest importance to the State and its citizens that the general medical practitioner should be up to date in all respects in medical science. General practitioners were often very poor. Medical men hardly ever died rich. He hoped the

Government would see their way to give facilities to general medical practitioners to come to London from time to time to revive and review their knowledge. He was disappointed that the Minister of Health had made no reference in his speech to the Welsh Board of Health, which was doing very fine work. He hoped the right hon. gentleman would give the Board every encouragement. He hoped that if Mr. Greenwood occupied his position this time next year he would be able to give the House a more hopeful, more optimistic, and more successful review of the work which the Ministry of Health had undertaken.

PURE MILK.

Mr. **OSWALD LEWIS** moved to reduce the vote by £100. He said that Lady Astor had referred to the subject of infant mortality. There was no single factor more calculated to affect the death-rate of young children than the purity or otherwise of the milk-supply. In this country the production, distribution, and sale of milk was watched at every stage, and as a result the nation got a very good supply of pure milk. The position in regard to imported milk substitutes, however, was not so satisfactory. The growing quantity of these substitutes which was being imported made this matter one of considerable importance. This country was one of the few countries where no minimum of milk fats was prescribed by law in respect of these milk substitutes. The Minister of Health stated that in his opinion such regulations were not necessary. He had also stated that these milk substitutes were in fact nutritious and did not contain anything likely to render them harmful as an article of diet. He (Mr. Lewis) was not sure that all members of that House were equally satisfied on that score. It was useless to spend money, time, and trouble in ensuring that the milk produced on our own farms reached the consumer in a pure condition if they were to take no precautions in regard to the steadily increasing proportion of the population who used imported milk substitutes of inferior quality.

Mr. **KINLEY** said in some areas it was suggested that applicants for relief were not fairly treated, and there was no medical standard of physical requirement. He appealed to the Minister of Health to consider whether he could not devise through his own medical officers some minimum physical standard to which all poor-law relief must conform.

Lieut.-Colonel **FREMANTLE** said the main problem in regard to milk in its relation to health did not lie in its cleanliness, although that was of importance; the main difficulty was to get the milk free from tubercle. Fifteen months ago he asked the Minister of Health if he would have an authoritative statement prepared by his department giving the main facts and conclusions with regard to bovine tuberculosis. The Minister of Health told him that the memorandum would be published, and the Parliamentary Secretary had later informed him that the memorandum was being printed and would be published at an early date. That was on Feb. 5th, but on April 14th the document had not been published. This was an instance of the dilatoriness in the Ministry of Health at the present time, and he hoped that when they took up a definite idea which had been proved to be helpful, they would push it through a little more quickly than they had done in the past. A new regulation had been made by which insured persons could not change their doctor without giving a quarter's notice. Some of the committees dealing with insurance considered that this was a most retrograde step. The medical practitioners did not ask for this restriction, and it had always been considered to be in the interests of both patient and doctor that there should be freedom of choice of doctor. The medical profession did not think that this change was advisable.

MEDICAL OFFICERS OF HEALTH.

The appointment of medical officers of health, especially of counties and county boroughs, was of great importance nowadays. At present those appointments were subject to inconvenient regulations by the Minister of Health. Hitherto the local authorities had had to make their own appointments separately and independently, and each local authority had its own staff. When a post of a medical officer of health was vacant the local authority advertised the appointment, but the conditions which were now imposed did not attract the best applicants. He wanted the Minister to see if he could not help in this matter. The changes which were necessary did not require any fresh legislation; all that was required was more coöperation with the local authorities concerned. He noticed that the senior appointments were limited to men under 40 years of age. That was one of the difficulties, and it was quite unnecessary to specify such an early age. When medical officers could hold these appointments up to the age of 60 years it seemed very unjust to limit them to applicants under 40 years of age.

Major **ELLIOT** said he could imagine no more important thing for a community to-day than to know whether the bone and the muscle of the people, the fibre of the nation, was becoming rotten or sounder, whether the health of the nation as expressed in tuberculosis statistics and infantile mortality statistics, and statistics for diseases such as cancer and diabetes was improving or not. After the long-continued stress of unemployment it was necessary to know whether it was being reflected in the physical constitution of the nation. Seldom had he heard the estimates of the Ministry of Health treated with such universal condemnation as they had been that day. Public health was not the only question that had been raised. The number of those in receipt of poor-law relief was still well over a million. In regard to housing the Minister of Health had ridden off on promises.

THE MINISTERIAL REPLY.

Miss **LAWRENCE** (Parliamentary Secretary to the Ministry of Health), replying to the debate, said although the figures of 1930 were not yet to hand, every indication pointed to the fact that 1930 was an exceptionally healthy year. Infant mortality had sunk to the lowest point ever known, and was now at the figure of 60. The claims on the approved societies showed a considerable rise for the first quarter of 1929, which was marked by the influenza epidemic. The claims were in round figures 15½ in 1928, 17¾ in 1929—due mainly to the influenza epidemic—and they were down now to rather over 15½. Cancer, unfortunately, was an exception to the general rule. They had been told that doctors objected to changes in the regulations which extended the period during which a patient might not change his doctor. As a matter of fact a doctor, if he chose, could let his patients go at any minute he liked. The medical profession had discretion in the matter. She hoped that the report on bovine tuberculosis would be published in a few days. The housing programmes of local authorities showed the immense increase of no less than 80 per cent. over the actual building last year carried out by those authorities. They were responsible last year for about 37,000 houses. Their programmes provided for an average of 67,000 houses a year for the next five years. In other words, the annual average would be considerably greater than the total attained during all the years since 1919.

The motion to reduce the vote was negatived by 199 votes to 72.

TOWN AND COUNTRY PLANNING BILL.

Mr. **GREENWOOD** (Minister of Health) in moving, on Wednesday, April 15th, the second reading of the Town and Country Planning Bill, said that the planning of built-up areas was a necessary corollary of any legislation designed to make a definite attack on the slums and arrange for the demolition of slum property. It was of vital importance that the areas which were cleared of slum property should be developed on sound, sane, and economical lines, and in the rehousing of slum dwellers it was important that the local authorities should act on a definite plan. He regarded planning as an important economic problem and as a means of national economy. The first clause of the Bill dealt with the extension of planning powers. It was made quite clear that planning should now be extended to built areas. It also extended the need for planning to rural areas. It was provided in Clause 3 that regional committees should make their regional schemes to be filled in afterwards by local authorities in Clause 9, with supplementary schemes. It was further laid down in Clause 13 that the details of a scheme could be approved by supplementary orders. Compensation would be excluded in the case of the prohibition of the use of land for a purpose likely to involve danger to the health of the neighbourhood or be seriously detrimental to it—such purposes, for example, as refuse dumps and so forth. As the law stood at present the local authority might claim one-half of the betterment which accrued from a town-planning scheme. He saw no reason why the local authority should not, under this scheme, claim 100 per cent. of the betterment, and that was so provided in Clause 19. The provision in the Bill in regard to garden cities and satellite towns was in principle that contained in existing legislation. If new garden cities were to be established and developed successfully they should be planned properly from the outset. He hoped that it might be possible to discuss the principles of the Bill in Committee with a considerable measure of agreement.

BETTER LATE THAN NEVER.

Mr. CHAMBERLAIN said that Mr. Greenwood had worked in the wrong order. The right hon. gentleman told the House that a planning Bill of this kind was a necessary corollary to plans for slum clearance or the rehousing of slum populations. He (Mr. Chamberlain) said that it was a necessary precedent to it, not a corollary. He was sorry that the right hon. gentleman did not bring in this Bill first and the Act of 1930 afterwards. However, it was perhaps not too late in this Bill to draw the attention of local authorities to the fact that in any housing operations that they might carry out as a consequence of slum clearance they must pay attention not merely to bricks and mortar but also to the questions of transport and of the proper commercial use of the sites at their disposal. Speaking generally of the measure Mr. Chamberlain said that he regretted that there had not been more productive and fruitful thinking on a subject which he believed to be of great importance to the housing of the people in the future and of the proper development of the country and the town.

After further debate the Bill was read a second time without a division. The money resolution in connexion with the Bill was afterwards agreed to in Committee.

HOUSE OF COMMONS.

THURSDAY, APRIL 16TH.

Change of Panel Doctor.

Mr. ALBERY asked the Minister of Health if he would consider amending the new regulation which restricted the right of insured persons to change their medical adviser.—Mr. GREENWOOD replied: The answer is in the negative.

Tuberculosis in South Shields.

Mr. EDE asked the Minister of Health if his officer who recently investigated the prevalence of tuberculosis in South Shields made any report on the incidence of this disease in those parts of the borough where the partition of houses into tenements had taken place; whether the officer made any report on the rents demanded for such tenements; and whether he had taken any action on the report.—Mr. GREENWOOD replied: The answer to the first and second parts of the question is in the negative. As regards the last part, I have at the request of the town council invited a number of local authorities in the north-east of England to send representatives to a conference for the purpose of considering the question of institutional accommodation for the treatment of tuberculosis in that area, and it is hoped to arrange for the conference to be held at an early date.

Opticians and Health Insurance.

Mr. GRAHAM WHITE asked the Minister of Health the total number of approved opticians, distinguishing between qualified and unqualified persons, under the national health insurance scheme.—Mr. GREENWOOD replied: I have no information as to the number of opticians who undertake the supply of optical appliances to insured persons entitled to ophthalmic benefit under the National Health Insurance Scheme. The regulations governing the administration of this benefit do not provide for the approval of opticians.

MONDAY, APRIL 20TH.

Medical Authorities and Commutation Applications.

Sir HERBERT CAYZER asked the Minister of Pensions whether he was aware that hardship was being caused to retired regular officers whose applications for commutation had been refused on medical grounds; and if he would consider placing such cases before the medical authorities' commutation board for a ruling decision, especially where officers were also in receipt of service retired pay and wounds pensions in addition to disability pension.—Mr. F. O. ROBERTS replied: Under the Pensions Commutation Acts and Regulations the Minister of Pensions is required to determine whether any application for commutation should be recommended to the Pensions Commutation Board for consideration, and regard is necessarily had to the officer's state of health and expectation of life. Where any medical advisers consider that the case is unsuitable on these grounds it is not possible for me to recommend it.

Unfit Houses in Walsall.

Mr. MCSHANE asked the Minister of Health in respect of the county borough of Walsall the number of houses certified as unfit for human habitation; and the number of houses proposed to be built under the Slum Clearance Act, 1930, during the next five years.—Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend is informed that 274 houses in the county borough of Walsall have been represented by the medical officer of health as being unfit for human habitation. The council propose to build 1000 houses under the Housing Act, 1930, during the next five years in addition to 300 houses under the Housing Act, 1924.

Cattle and Intradermal Test.

Brigadier-General CLIFTON BROWN asked the Minister of Health whether his attention had been drawn to the uncertainties of the intradermal test on cattle for tuberculosis; and if, in view of its unreliability, he would take steps to standardise the tuberculin on the market so that all tests could be carried out with the same serum.—Miss LAWRENCE replied: My right hon. friend is advised that the intradermal test is the best form of the tuberculin test under ordinary farm conditions, but that the results obtained cannot be relied on unless tuberculin of sufficient potency is used. My right hon. friend is considering the question of the standardisation of tuberculin in consultation with my right hon. friend, the Minister of Agriculture and Fisheries.

Government and Hospital Sweepstakes.

Sir WILLIAM DAVISON asked the Home Secretary whether in view of the information recently supplied to him and also of the losses which were being suffered by British hospitals by the falling off of subscriptions since the recent Irish Free State sweepstakes in aid of Dublin hospitals, he was now prepared to set up a committee to investigate the conditions and safeguards which would be necessary if lotteries were to be permitted as a method of raising money for approved public purposes.—Mr. CLYNES replied: I have delayed coming to a decision on this question in the hope that I might receive some definite indication of the attitude of those responsible for the more important charities. Such indication as I have received seems on the whole adverse. I think it will be wise to defer a decision for some time longer, particularly as there can, of course, be no question of legislation this session.

Insured Persons and Dental Benefit.

Mr. R. J. RUSSELL asked the Minister of Health the number of insured persons eligible to receive dental benefit under the scheme of additional benefits; the number of insured persons who actually received such benefit during the last year for which figures were available; the cost to the approved societies of the benefit in that year; and the total cost of the treatment given, inclusive of that part of the cost paid by the insured persons themselves.—Mr. GREENWOOD replied: The number of insured persons in England and Wales who were eligible in 1930 to receive dental benefit is estimated at approximately 10,500,000. Of these the number who actually received the benefit is believed to be rather over 1,000,000. The cost of the benefit to approved societies in 1930 was, roughly, £2,100,000. As precise information is not available as to the amount paid by insured persons themselves, it is not possible to state the total cost of the treatment given.

TUESDAY, APRIL 21ST.

Blind Persons Act Administration.

Sir NICHOLAS GRATTAN-DOYLE asked the Minister of Health the cost of administering the Blind Persons Act, 1920, in England and Wales; the total number of registered blind persons in England and Wales on March 31st, 1931; the total number of blind persons between the ages of 50 and 70 years, and the number who were in receipt of blind old-age pensions, stating the reason why the remainder were not being granted pensions; the total number of blind old-age pensioners over 70 years of age; the number of blind persons in England and Wales under the various age-groups: 0–5 years, 5–16 years, 16–21 years, 21–30 years, 30–40 years, and 40–50 years; the total cost of pensions paid to persons under the Blind Persons Act, 1920; and the number of blind persons in receipt of poor-law relief and the average amount paid.—Mr. GREENWOOD replied: No complete figures are available of the total cost of administering the Blind Persons Act, 1920. The total number of registered blind persons in England and Wales was 52,727 on March 31st, 1920, the latest date for which official figures are at present available. According to unofficial figures obtained from the Counties' Associations for the Blind there were 56,853 registered blind persons on March 31st, 1930. Of that number 22,002 were between the ages of 50 and 70, and 10,018 were in receipt of blind old-age pensions. The estimated number in receipt of such pensions on March 31st, 1931, was 20,300. The remainder were not in receipt of pensions, either because they had not applied for a pension or because they did not comply with the statutory conditions for a pension. The number of blind old-age pensioners over the age of 70 is not known, because after attaining that age blind pensioners rank as ordinary old-age pensioners, "blindness" ceasing to be a statutory condition for a pension. The following Table gives the number of blind persons in England and Wales on March 31st, 1930, under the age-groups mentioned, according to the unofficial figures referred to above:—

Ages.	Number.	Ages.	Number.
0–5	267	16–21	1,637
5–16	2,401	21–50	14,354

Separate figures are not available for the age-groups 21–30, 31–40, and 41–50. The total cost of pensions paid to persons in England and Wales under the Blind Persons Act, 1920, for the year ended March 31st, 1931, was £512,000, and the estimated cost of administration for that year was £12,500. The information asked for in the last part of the question is not available.

Spotted Fever at Aldershot and Catterick Camps.

Mr. D. G. SOMERVILLE asked the Secretary for War if the military camp at Aldershot was now completely free from spotted fever; if cases were reported from Catterick camp; and whether there was any similar epidemic in other camps in England.—Mr. T. SHAW replied: During the present month there have been two fresh admissions to hospital at Aldershot in respect of cerebro-spinal fever. As regards Catterick, there have been four admissions during the present year. At no military centre other than Aldershot and Catterick have there been more than three cases during the present year, and there has been no epidemic at any military centre, sporadic cases only having occurred. The hon. Member does not, I hope, think that this is a disease occurring only among troops; it has, unfortunately, occurred also among the civil population.

Dunfermline College of Hygiene.

Mr. WATSON asked the Secretary for Scotland whether a decision had yet been arrived at respecting the proposed transfer of students from the Dunfermline College of Hygiene and Physical Education; and whether, in view of the opposition the suggestion had aroused and the trouble and expense the establishment of the college had caused to the Carnegie Dunfermline Trust, he could see his way to continue the work of the college as at present.—Mr. ADAMSON replied: It has been decided that as from October next the men students shall receive their training at the Glasgow Training Centre, where the necessary provision is being made. As regards the women students, I understand that the question whether they should ultimately receive their training at Dunfermline or elsewhere is likely to be considered at an early date by the National Committee for the Training of Teachers in conference with the Carnegie Dunfermline trustees, who act as managers of the college. In the meanwhile steps are being taken for the appointment of a woman principal to supervise the training of the women students at Dunfermline.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

THE following appts. have been notified:—Surg. Lts. V. G. Horan to R.N. Hospital, Plymouth, and R. C. Foster to *Bryony*.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Sub-Lts. J. F. M. Milner and S. O. Suggitt to be Surg. Sub-Lts.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. W. G. Maydon retires on retd. pay.

Maj. (temp. Lt.-Col.) J. E. M. Boyd to be Lt.-Col., vice Lt.-Col. W. G. Maydon.

Maj. M. O. Wilson to be temp. Lt.-Col.

F. V. Cant is granted a temp. commn. in the rank of Capt.

TERRITORIAL ARMY.

Capt. A. W. Wakefield having attained the age-limit retires, and retains his rank, with permission to wear the prescribed uniform.

Capt. C. B. Macleod from 13th Highland Light Bde., R.A., T.A., to be Capt.

Lt. R. Anderton to be Capt.

M. C. Hounsfield (late Offr. Cadet Serjt., Cambridge Univ. Contgt., Sen. Div. O.T.C.), and James Morissey (late Offr. Cadet Lce.-Corpl., Liverpool Univ. Contgt., Sen. Div., O.T.C.) to be Lts.

Supernumerary for Service with the O.T.C.—Capt. H. E. A. Boldero resigns his commn.

INDIAN MEDICAL SERVICE.

J. Acheson to be Capt.

Bashi Lal Taneja and Hoc Min Sein to be Lts. (T.C.).

Lt.-Col. D. G. Rai retires.

ROYAL AIR FORCE.

Flight Lt. R. J. I. Bell is transferred to the Reserve, Class D. (ii).

HONORARY APPOINTMENTS TO THE KING.

The King has approved the appointment of Major-General H. Boulton, C.B., C.B.E., I.M.S. (Honorary Surgeon to the Viceroy of India), as Honorary Surgeon to the King; and Colonel C. W. F. Melville, I.M.S., as Honorary Physician to the King.

ORDER OF THE NILE.

The Insignia of Commander of the Order of the Nile has been conferred upon Major Joseph Clinton Collins, R.A.M.C., by the King of Egypt in recognition of valuable services rendered by him.

DEATHS IN THE SERVICES.

Major-General George Francis Angelo Harris, C.S.I., who died on April 16th in London at the age of 75, was the son of the late Major-General C. S. Harris of the Bengal Staff Corps, and received his early education at Bedford Modern College. Later he entered St. George's Hospital, and after qualifying with the L.R.C.P. Lond. and M.R.C.S. Eng., joined the Indian Medical Service in 1878, and saw service in the second Afghan War (medal). In 1893 he obtained the M.R.C.P. Lond., in 1902 the M.D. Durham, and obtained the F.R.C.P. Lond. in the following year. Among the appointments which he held were those of professor of materia medica at the Calcutta Medical College, and physician to the College Hospital, Inspector-General of Civil Hospitals in the Punjab and the United Provinces. He was also employed on medical work in Bengal. In 1911 he received the C.S.I., and three years later was made hon. surgeon to the King and to the Viceroy of India. He married in 1883 Alice, daughter of General A. E. Campbell, of the Bengal Staff Corps, by whom he had two sons and four daughters.

PLYMOUTH HOSPITALS.—An appeal is being made for at least £25,000 beyond the amount already subscribed to cover the cost of the extensions to the South Devon and East Cornwall and Royal Albert Hospitals. These two institutions, the Central Hospital and the Royal Eye Infirmary, together last year treated 5419 in-patients and 16,773 new out-patients, in addition to the work done at the city municipal hospital.

OBITUARY

THEODORE DYKE ACLAND, M.D., F.R.C.P.Lond.,

CONSULTING PHYSICIAN TO ST. THOMAS'S HOSPITAL.

WE regret to record the death of Dr. Theodore Acland, which occurred at his residence 19, Bryanston-square, on Thursday, April 16th, in the eightieth year of his age.

Theodore Dyke Acland was the younger son of Sir Henry Acland, the famous Regius Professor of Medicine at Oxford. He received his school education at Winchester, whence he proceeded to Christ Church, Oxford, and completed his academic studies with a first-class in the natural science schools in 1874. Entering at St. Thomas's Hospital, he graduated in medicine in 1880, taking the degree of M.D. in 1883. After filling the usual appointments he attended post-graduate courses at Leipzig and Berlin, and in 1882 was appointed demonstrator of physiology in the St. Thomas's Hospital Medical School. In 1887 he was elected to the assistant staff and from that time his medical career was a very full one and active along several lines.

DR. ACLAND.

[*Photograph by J. Russell & Sons.*

While still working in the medical school he was sent by the Foreign Office to Egypt, for in 1883 a serious epidemic of cholera was causing much anxiety there. He remained in Egypt for some time serving with the Egyptian Army of which he became P.M.O. and where his services were rewarded with the Imperial Order of the Medjidie, while he also received the personal thanks of the Khedive. On returning to England he took up his duties at St. Thomas's Hospital, being also appointed to the Brompton Hospital for Consumption and Diseases of the Chest, and his work in both institutions marked him out as a high clinical authority. His qualities of character assisted him alike in the treatment of his patients and in securing from his house officers the best they could bring to their work. On the appointment of the Royal Commission on Vaccination, which sat for seven years from 1889, Acland was elected a member of the Commission and served throughout its protracted sessions. He brought an analytical mind to bear on the problems, both scientific and social, presented by the vaccination question, and those who have studied that report, and the documents presented to it, no less than the evidence, will recall the need that was required for wisdom and moderation in arriving at the conclusions.

In 1897 King Edward VII.'s Hospital Fund for London was instituted and Acland became a member of the visiting committee, while in 1906, on the foundation of the King Edward VII. Sanatorium he was elected physician to the institution; in both cases his selection for the duty was due to his repute as a fair and learned man, while his wide social connexions were of value to the organisations.

Acland was influential in the affairs of the Royal College of Physicians of London. Elected to the Fellowship in 1889, after the minimum period as a member, he was a member of council for two years, censor for two years (1913–15), and an examiner in medicine at the Conjoint Board. His services as an examiner were also requisitioned by the India Office, and by the Universities of Oxford (where he was also a member of the Board of the Faculty of Medicine), of Cambridge, Manchester, and Leeds. His sympathetic bearing no less than his clear-cut knowledge recommended him to the delicate task of sound examining, and in 1906 he renewed in this way his acquaintance with Egypt by becoming the first assessor of examinations to the Cairo Medical School. He was also elected a member of the Egypt and Sudan London Medical Board and medical officer to the Sudan Government. For these services he received, in addition to the Order of the Medjidie, the Imperial Osmanieh Order and the Order of the Nile.

During the war Acland's work was enthusiastically performed. Appointed a Lieut.-Col. R.A.M.C. (T.) his counsel was called upon in many directions both during and after hostilities. He was a consultant physician to the Ministry of Pensions, and to the National Council of the Y.M.C.A. in t efforts to meet the cases of the discharged and disabled soldiers, while he was also concerned in the provision of housing for disabled service men—the Seal Foundation. He put his energy and heart into all these schemes for the relief and betterment of the victims of war, and many will be mourning in him the loss of a friend.

Acland was not a frequent writer or a controversialist, though he made a considerable number of useful communications upon many subjects allied to medicine. To Allbutt and Rolleston's System he contributed the articles on vaccinia, actinomycosis, and subphrenic and other forms of peritoneal abscess; he edited the works of Sir William Gull, and for several years the St. Thomas's Hospital Reports.

The following tribute from Dr. V. S. Hodson, once Dr. Acland's house physician, gives a sympathetic picture of him: "From the day, now nearly 30 years ago, when I took up duty as Dr. Acland's house physician, friendship began between us, and as the years passed it grew and strengthened and, without setback or cloud, has been one of my most treasured possessions, and is now a hallowed memory. It would be difficult for me to say how much I owe him, whether as a teacher or friend, or as an example to be followed. From those far off days of hospital association I learnt many things from him, and I have never worked for anyone more appreciative or stimulating. His gentleness, courtesy, and sympathy in dealing with his patients were a permanent lesson, and his happy way of getting the best out of his subordinates by just expecting it and by relying on them to produce it was as successful as it was pleasant. I once heard one of his colleagues say that all Dr. Acland's geese were swans. I believe this to be more or less true and to mean, in reality, hat he always thought the best possible of those who worked for him, with the result that the geese did their outmost to prove him right, and not disappoint his trust. No trouble was too great for him to take on behalf of a junior, for him his large and weighty influence was freely used. His charities were innumerable and almost wholly anonymous."

Dr. Acland married Caroline Cameron, the only daughter of the great physician Sir William Gull; she died in 1929, and one son survives, Captain Theodore Gull Acland.

JAMES LORRAIN SMITH, M.D. Edin., F.R.S.

Prof. J. Lorrain Smith died on April 18th. He had been ill for some months and had been relieved of his duty as Dean of the Medical Faculty.

PROF. LORRAIN SMITH.

Block lent by the "Scotsman."

Lorrain Smith was a graduate in arts of Edinburgh University and achieved distinction in philosophy. In 1885 he won the Ferguson scholarship in philosophy which, at that date, was the blue riband among competitive prizes open to graduates of the four Scottish universities. He had a very distinct philosophical bias and, had he kept to this line, he could have achieved a distinction as great as he ultimately did in medicine. But in 1885 he entered medicine at Edinburgh and took his M.B., C.M. in 1889 and his M.D. in 1893. After graduation, he studied for a period with Prof. Burdon Sanderson at Oxford, himself one of the rare philosophic minds in the physiology of that day. Afterwards, he worked under Prof. C. S. Roy at Cambridge, where he held the John Lucas Walker scholarship in pathology. He spent some time at Strassburg and Copenhagen. His earlier work was mainly in physiological research; but, while maintaining a strong interest in physiology, he took to pathology and the problem of all his teaching days was how to exhibit the physiological groundwork of pathology. He had acted at Cambridge as demonstrator in pathology, and later became first lecturer and then professor of pathology at Queen's College, Belfast. From Belfast he was appointed in 1904 professor of pathology in the University of Manchester and honorary pathologist to the Manchester Royal Infirmary. Eight years later he was appointed to the chair of pathology in Edinburgh University. While still in Manchester, he was a member of the General Medical Council and, later, he represented Edinburgh University on the Council.

Lorrain Smith had been a prominent and popular figure in British pathology for the last 30 years, in an important period of transition and development, and his loss will be deeply felt by his fellow-workers on personal no less than scientific grounds.

In his laboratory work he was at first closely associated with Prof. J. S. Haldane; they investigated the alleged mysterious poison in expired air, and the results were published in the first volume of the *Journal of Pathology and Bacteriology* when it was founded by the late Sir German Sims Woodhead and Mr. Pentland in 1892. He worked, too, at hæmoglobin in its various aspects, carbon monoxide poisoning, the secretion of oxygen by the lungs, and devised the first satisfactory method of determining the blood volume in man. From this last emerged his most fundamental discovery, worked out in Belfast—that the anæmia of chlorosis is due to the dilution of the blood with an excess of plasma, while in pernicious anæmia there is a real deficiency of hæmoglobin (*Trans. Path. Soc. Lond.*, 1900, li., 311). He showed the actual existence of a persistent state of anæmic plethora which Cohnheim and others had tried in vain to produce experimentally, and thus threw an entirely new light on the pathology of the disease. The new questions which his discovery raised have not been solved, and now that chlorosis has practically disappeared probably never will be. By this time Lorrain Smith was a professor of pathology. His further work lost the "physiological" tone which was so welcome, and ran along more conventional lines. The second investigation for which he will be remembered was pursued chiefly in Manchester, and mainly in collaboration with Dr. W. Mair and to a less extent with the late Dr. C. Powell White. It dealt with the nature and especially the microscopical identification of lipoids, and out of it came two well-known histological methods—the staining of fresh fat with nile blue sulphate which distinguishes neutral fats from fatty acids, and the extension of Weigert's bichromate-hæmatoxylin process for myelin to the examination of tissue lipoids. In this work he secured the useful collaboration of his chemical colleagues in the University of Manchester. Without counting a number of minor researches, Lorrain Smith has certainly left his mark on technical pathology.

But he will be remembered by the younger generation, perhaps particularly, as a sane, idealistic, and always friendly guide and leader—rather dreamy and vague sometimes in university affairs, by nature fond of the traditional methods of diplomacy, but always steadfast in his belief in sound learning and the pursuit of knowledge; no student or graduate can have ever got the idea from him that university education was not worth while. He had a singular faculty for encouragement. He fortunately had rather exceptional opportunities for developing his ideals. He went to Manchester to take over the pathological laboratory when the chair was divided and Delépine restricted himself to bacteriology, and in Edinburgh, in succession to Greenfield, he was the first professor of pathology without clinical beds to distract his attention. He also had much to do with the founding of the Pathological Society of Great Britain and Ireland in 1906 and the Pathological and Bacteriological Laboratory Assistants' Association in 1912—two organisations which have effected something like a revolution in British pathology.

All Lorrain Smith's research showed the philosophic grasp of his mind. He was never lost in detail. He had always before him the fundamentals of biology; indeed, it would not be too much to say that his primary interest in life was the philosophical interpretation of biological phenomena. In his work, as dean of the medical faculty at Edinburgh, he devoted himself to the task of correlating the teaching of biology with the teaching of anatomy, pathology, bacteriology, and practical medicine. He saw the same fundamental principles in them all and, in the end, persuaded several of his colleagues to try the experiment of parallel teaching of the various subjects from the different standpoints. This, of course, was not entirely possible under university conditions, but in some of the classes the system was established and the results were good. In his own teaching he put the greatest stress on securing for his students direct contact with the actualities. He would give them a problem in some morbid condition, placing before them the history of the case, the system of treatment, the morbid products from the post-mortem table, and require them to correlate all these into a coherent account of the problem as a whole. This kind of teaching was slow from the examination standpoint; but his students informed him again and again that the most fascinating part of their curriculum had been this "research method" of learning pathology. On one occasion a distinguished American medical man put to him the question how it was that the professors in the Scottish universities not only did research work but also taught, while in America research and teaching were looked on as two distinct lines. Lorrain Smith's reply was that in his own experience he found that constant work in research enabled him to enrich his teaching in a way otherwise impossible, and that he continued his research in order that he might teach better. He maintained that research kept the professor alive in his teaching and the teaching continually stimulated him to further research. This was certainly so in his own case and it is a principle not to be lost sight of. It is true that many of the Scottish schools and some of the best research in several departments have emerged from men who were also well occupied in the teaching of large classes.

A colleague writes: "In the journeys from London to Edinburgh, following the six monthly meetings of the Medical Council, Lorrain Smith and his friends usually discussed biology, its place in the curriculum, how this school, how that school were advancing along special lines, and how far it was possible to have the whole curriculum based on a thoroughly taught and thoroughly understood study of biological ideas. And biology he always used in the larger sense as including physiology. He was thoroughly against the bulkhead idea of separate subjects and he wished to see the whole curriculum developed as a system of biological ideas applied in the practice of medicine. A favourite maxim was 'Get to the ætiology and then your treatment will follow as a deduction.' Of the friends that knew him in his early philosophical days, this type of reasoning was very familiar and it was a joy to talk with him on those subjects.

"He was not a mere dreamer, although his mind never rested from the study of metaphysics and the larger principles of science. He was also a man of action. As dean of the faculty, he took particular pains to direct the individual life, and many a man owes his good grasp of medicine to Lorrain Smith's direction.

"Among his minor pieces of work was the experimental invention of eusol. The primary idea of this well-known antiseptic was to secure a powder that could be immediately sprinkled on a wound where the moisture would be enough to set free some antiseptic material. The active principles of eusol are chlorine and boracic acid. Later, the powder was supplemented by the solution and, with due attention to freshness, this solution has given excellent results. The name, it is understood, is simply the initials of Edinburgh University, linked to the syllable 'sol.'

"Lorrain Smith was a humanist in the widest sense. At Edinburgh he took his part in constructing the University Settlement and the School of Social Study, and he lent himself in various ways to the promotion of social movements. He also took a leading place in the movement for the reading of verse. His knowledge of ballad literature was extensive and his sensitiveness to literary form of every kind was exceptional. In culture and accomplishments he belonged rather to the old school that included Duncan, Abercromby, and John Brown. He thought of life in its greater relations. Among philosophers he counted as a technical philosopher; among scientific men he had proved his quality as an investigator, and, on the practical side, he showed a profound knowledge of sound teaching method and constructive administration."

Prof. Lorrain Smith was a son of the late Rev. Walter Smith, Half Morton, Dumfriesshire. He leaves a widow, one son, and four daughters.

MEDICINE AND THE LAW.

Negligence Action against Surgeon.

IMPORTANT observations as to the duties of a surgeon were made by Lord Justice Scrutton on April 20th in dismissing a surgeon's appeal against an adverse verdict of negligence. At Shrewsbury Assizes a special jury found that the surgeon had been negligent in leaving a swab or pack in the patient's body in the course of an operation; as the result the patient died and £1500 damages were awarded to the widow, £500 to a child, and £100 as special damages. The defence was a denial of the negligence and a reliance on the fact that it was the duty of a skilled nurse to count the swabs or packs as they were removed from the patient's body. The Medical Defence Union acted for the surgeon.

Lord Justice Scrutton does not say that the surgeon may not rely upon an assurance by a competent nurse that a tally has been kept of the swabs, that all the swabs have been removed, and that therefore he need himself make no further search. The Lord Justice merely points out that, if the surgeon received no such assurance, he cannot rely upon that defence. "In answer to the question put to them, the jury found that the evidence was to their minds not satisfactory that the doctor had received the necessary assurance." Lord Justice Scrutton appears to assume that, in the absence of such an assurance from a competent person, the surgeon is personally responsible. "It is clear that the only person who put the swabs in and selected the places where they were to be placed was the doctor. He alone knew where he had put them. . . When the operation was completed, it still remained for the doctor to take out the swabs which he had put in." Almost every jury would find that it was careless to leave a swab in the body. The Court of Appeal had only to consider whether the verdict was one at which the jury could reasonably have arrived, or on the other hand whether it was one which the Court could not uphold. In the Lord Justice's opinion the verdict was not one with which the Court could interfere. His colleagues concurred and the appeal was dismissed. It thus appears that, if the Court of Appeal is right, the duty of counting the swabs does not naturally fall on the skilled nurse but remains primarily the duty of the surgeon. The surgeon may rely on a report from the skilled nurse that all swabs have been counted, that the tally is correct, and that, therefore, he need not himself make any further search. But he must, it seems, obtain this assurance and be able to prove definitely that it was given if he is to rely on it as a defence.

MEDICAL NEWS

University of London.

Forthcoming Lectures.—Three lectures on the Pharmacology and Therapeutics of Lead Colloids with particular reference to their use in the treatment of neoplasms will be given at King's College, Strand, at 5.30 P.M., on May 7th, 8th, and 11th by Dr. W. J. Dilling, professor of pharmacology in the University of Liverpool.—Dr. R. J. Lythgoe will give six lectures on Special Sense Physiology, at University College, Gower-street, at 5 P.M., on Thursdays, from May 7th to June 11th inclusive.

University of London Medical Graduates Society.

The annual London dinner of this society will be held on Tuesday, May 12th, at the Langham Hotel, Portland-place, W., at 7 for 7.30 P.M., with Sir John Rose Bradford, the President, in the chair. Medical graduates can obtain tickets from the secretaries of the society at 11, Chandos-street, Cavendish-square, W.1, before May 8th.

St. Marylebone General Dispensary.

The twenty-fifth anniversary of the opening of the infant welfare clinic will be celebrated at this dispensary on Wednesday, April 29th, at 5 P.M. (tea 4.30 P.M.). The speakers will include Miss Susan Lawrence, Parliamentary Secretary to the Ministry of Health, Dr. Eric Pritchard, Dr. Charles Porter, Mr. W. McAdam Eccles, F.R.C.S., and Dr. J. F. Halls Dally.

St. Mary's Hospital Institute of Pathology.

A course on pathological research in its relation to medicine will open at the Institute of Pathology and Therapeutic Research, St. Mary's Hospital, London, W., at 5 P.M., on May 5th, with a lecture by Sir Almroth Wright, F.R.S., principal of the Institute, on the Organisation and Methods of Medical Research. The course will continue at the same hour on Tuesday afternoons until June 23rd, and the lecturers will include Prof. John Mellanby, F.R.S. (Recent Work on Blood Coagulation); Colonel S. P. James, F.R.S. (the New Method of Studying Malaria); Dr. Bernard Hart (the Causation of Neurotic Disorders); and Dr. André Gratia, of Brussels (the Shwartzman Phenomenon). The lectures are open to members of the medical profession and medical students, without fee.

Congress of Military Medicine and Pharmacy.

The Sixth International Congress of Military Medicine and Surgery and Pharmacy meets at The Hague from June 15th to 20th under the presidency of Dr. J. C. Diehl, director-general of the Army Medical Services of the Netherlands. The principal subjects of discussion will be the recruitment and training of medical and pharmaceutical officers, the psychoneuroses of war, the preparation and conservation of medicine in tubes and their use by military medical services, the arrest of hæmorrhage on the battle-field and standards of material for this purpose, and the sequels of wounds of the teeth and lower jaw. A historical exhibition is being organised in connexion with the congress. The secretary-general is Jhr. R. Sandberg van Boelens, and the office is at 3, Surinamestraat, The Hague. Travel arrangements are in the hands of Thos. Cook and Son, Berkeley-street, Piccadilly, London, who will supply particulars of accommodation and facilities for the journey.

Congress of Radiology.

The Third International Congress of Radiology will take place in Paris from July 26th to 31st under the honorary presidency of Madame Curie and the executive presidency of Dr. Antoine Béclère. During the opening meeting Prof. G. Forssell (Sweden) will speak on the Social Struggle against Cancer. The four principal subjects of the congress and their introducers are the radiological examination of the mucosa of the digestive tract (Dr. Cole, U.S.A.); the pre- and post-operative treatment of cancer of the breast by radiation (recurrency and *metastases* excepted) (Dr. J. E. A. Lynham, England); the radiological examination of the urinary apparatus by excretion of opaque substances (Prof. F. Haenisch, Germany); and the radiotherapy of inflammatory diseases (Prof. E. Milani, Italy). More than 300 communications are announced and will be divided between sections devoted to radiodiagnosis, rontgen and curietherapy, radiophysics, radiobiology, electrology, and natural and artificial heliotherapy. Those attending the congress may visit various holiday and health resorts in France at reduced rates. Membership is open only to members of radiological societies and persons accepted by such societies. Full particulars may be had from the office of the congress at 122, rue la Boëtie, Paris VIIIe.

University of Birmingham.

The Withering lectures will be given by Sir Hubert Bond, H.M. Commissioner of the Board of Control, at the Medical Faculty Building, Edmund-street, on Wednesdays, May 13th and 27th, and June 10th, 17th, and 24th at 4 P.M. The title chosen is Some Correlations between General and Psychological Medicine.—The Ingleby lectures, on Maternal Disablement, will be delivered at the same hour and place on Thursdays, May 21st and June 4th, by Mr. W. Blair Bell, professor of obstetrics and gynæcology in the University of Liverpool.

Post-graduate Demonstrations will be given at the General Hospital, Birmingham, on Tuesdays, and at the Queen's Hospital on Fridays, at 3.30 to 5 P.M., starting on Tuesday, April 28th. Particulars may be had from the Clerk to the Clinical Board of the University, Edmund-street, Birmingham.

Post-graduate Course at Liverpool.

At the Liverpool and District Hospital for Diseases of the Heart there will be a post-graduate course in cardiology from May 4th to 15th from 3.30 to 5.30 P.M. each week-day except Saturday. The course is limited to 20 members and application should be made to Miss Lewis at the hospital.

Journées Médicales Coloniales.

In connexion with the International Colonial Exhibition in Paris this summer there will be a congress of colonial medicine from July 22nd to 30th, under the presidency of Prof. L. Tanon. The secretary-general is Dr. Boyé, 112, Boulevard Haussmann, Paris.

Annual Conference on Social Work.

The conference this year is organised by the Association of Hospital Almoners, and will be held at Bedford College, Regent's Park, during the week end, April 25th–27th. The main theme of the discussion will concern the development in social work since the beginning of the present century. The principal meeting on April 25th will be addressed by Prof. Carr-Saunders, when Sir Harold Morris, K.C., President of the Industrial Court, will be in the chair. Prof. Cyril Burt, D.Sc., will address a meeting on April 26th on the new methods of treating the "Difficult Child."

Medical Tour in Spain.

A third tour for medical men to the spas and climatic resorts in the north of Spain, to last ten days, is being arranged. The party will leave Santander about the middle of July for Covadonga, Pics de l'Europe, Cote Asturias, Coruña, Santiago de Compostela, Vigo, and other places. It is hoped that certain Portuguese stations may also be visited. The cost from Santander will be 1200 French francs. Further information may be had from Dr. Mariano Mañeru, Ronda del Condo Dunque 4, Madrid. The list will close on or before May 15th.

Royal Sussex County Hospital.

A new theatre block was opened at this hospital by Lord Moynihan on April 16th. Events during the past few years have shown the necessity for the new operating theatres; there were 3212 in-patients during 1930, and no fewer than 2535 operations in the then existing theatres. The total cost of the new block has been £15,500, towards which a grant of £5000 was received from the estate of Mr. Bernhard Baron.

Addressing a large gathering, Lord Moynihan declared that he did not share the opinions of those who were saying that the principle of voluntarism in connexion with hospitals was decrepit and moribund, out of tune with the times, and not fulfilling its obligations to the community. The voluntary system in this country, outside London, had an income of £1,250,000 more than its expenditure, and was adding not fewer than 1000 beds every year to the number of those already in use in hospitals. If a business firm was doing this the word moribund would hardly be suggested as appropriate. In his judgment the voluntary principle was not dead; it was still in its infancy. It did, however, require a much better organisation than it had ever yet received in the great majority of towns throughout the country. Having described the functions of hospitals as "the criminal investigation department, where the secrets of disease are searched out," Lord Moynihan proceeded to pay a warm tribute to both doctors and nurses, incidentally hoping that there would be more adequate remuneration for nurses and greater provision for their future. Speaking of the new theatre block, he said he had never seen anything better in any institution that he had visited in his life. Moreover, the whole spirit of the hospital was quite admirable. After being appointed a life governor of the hospital, Lord Moynihan accepted for the operating theatres fund a cheque for £55 10s. contributed by the nursing staff.

New Public Assistance Hospital at Bromsgrove.

Worcestershire County Council is about to erect a new hospital of 100 beds at Bromsgrove.

Paying Patients at Hendon.

A new block of buildings costing nearly £20,000 is to be added to Hendon cottage hospital for the provision of wards for paying patients.

Central London Ophthalmic Hospital.

The annual report states that a clinic for patients insured under the National Health Insurance Act has been started. Last year subscriptions increased, but endowment, equipment, and maintenance are causing the governors some anxiety. The average weekly cost of maintaining a patient was £2 14*s.* 7*d.*

Donations and Bequests.

By the will of the late Mr. W. Cameron of Kilmarnock, the Kilmarnock Infirmary will receive £10,000, the Royal Infirmary, Glasgow, the Royal Western Infirmary, Glasgow, and the Victoria Infirmary, Glasgow, £2000 each, the Cancer Hospital, Glasgow, £1000, and the Eye Infirmary and the Samaritan Hospital £500 each. After large sums to other charities half the residue of the property will go to the Kilmarnock Infirmary.

National Association for the Prevention of Tuberculosis.

The seventeenth annual meeting of this Association will be held at Margate from June 25th to 27th, with Sir Arthur Stanley in the chair. The subject of the conference is the protection of the child from tuberculosis, and on the first morning short introductory addresses will be given by Sir Robert Philip, Dr. Eugene L. Opie (U.S.A.), and Dr. Letitia Fairfield. At subsequent sessions the speakers will include Dr. Reginald Jewesbury, Dr. Nathan Raw, Dr. R. Stenhouse Williams, Prof. S. Lyle Cummins, Sir Henry Gauvain, Dr. T. R. Elliott, Dr. R. H. Crowley, Dr. Midgley Turner, and Dr. L. S. T. Burrell. Visits will be paid to many local institutions.

King Edward's Hospital Fund.

In aid of this fund a series of "Indictments" will be held at the London School of Economics, Houghton-street, Aldwych, W.C., at 5.30 P.M., on Tuesdays, from May 5th to June 16th. At the first Mr. St. John Ervine will defend himself against the charge of being unduly critical, the prosecutor being Lady Rhondda and the judge Mr. Theobald Mayhew. At the second, Father Ronald Knox will be charged with being "Torquemada" of the *Observer* and fraudulently concealing the fact, and at subsequent meetings Miss Megan Lloyd George will be accused of following in father's footsteps, Mr. Gilbert Frankau of defaming the modern young person, and "George A. Birmingham" of encouraging illiteracy. Tickets may be had from the secretary of the fund, 7, Wallbrook, E.C. 4, or at the doors.

Appointments

CADDY, ADRIAN, M.D. Lond., F.R.C.S. Eng., has been appointed Surgeon to the Royal Westminster Ophthalmic Hospital.

MANNERS, R., M.B., B.S. Durh., Hon. Physician to the Stockton and Thornaby Hospital.

The Ross-shire County Council have appointed Dr. DANIEL JOHNSTONE, Assistant Medical Officer of Health with school inspection duties, and Dr. FRANCIS SUTHERLAND, Assistant Medical Officer of Health.

London County Council: AVERY, J. C. H. (Miss), L.R.C.P., Lond., M.R.C.S., Assistant Medical Officer, St. Benedict's Hospital. PURVES, J. E., M.B., Ch.B.Edin., F.R.C.S. Eng., Senior Assistant Medical Officer, New End Hospital. WOOD, J. L. M., L.R.C.P. Lond., M.R.C.S., L.M.S.S.A., D.P.H., Assistant Medical Officer, New End Hospital. NIGHTINGALE, G. S., L.R.C.P. Lond., M.R.C.S., Assistant Medical Officer, Queen Mary's Hospital, Sidcup.

Certifying Surgeons under the Factory and Workshop Acts: ATKEY, P. J., L.R.C.P. Lond., M.R.C.S. (Woking); GROOME, W., M.B., C.M. Glasg. (Margate); PROUDFOOT, MARY E., M.B., Ch.B. St. And., and SAUNDERS-JACOB, E. VIRGINIA, Asst. Medical Officers, Woolwich Borough Council.

Vacancies

For further information refer to the advertisement columns.

Bangor, Caernarvonshire and Anglesey Infirmary.—Hon. Surg.

Bath, Royal United Hospital.—Asst. H.S. £120.

Birkenhead General Hospital.—H.P. £100.

Birmingham, Dudley-road, Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham, Queen's Hospital.—Cas. H.S. £70.

Birmingham Royal Cripples Hospital.—H.S. At rate of £200.

Birmingham University, Faculty of Medicine.—Chair of Anatomy. £1100.

Bradford Royal Infirmary.—H.P. and H.S. Each £150.

Brighton, Royal Alexandra Hosp. for Sick Children.—H.P. £100.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Burton-on-Trent, County Borough.—Deputy M.O.H. &c. £600.

Burton-on-Trent General Infirmary.—Sen. and Jun., H.S.'s [illegible] and £150 respectively.

Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Third Res. H.S. At rate of £75.

Charing Cross Hospital, Strand, W.C.—Clin. Asst. to Skin Dept.

Chelsea Hospital for Women, Arthur-street, S.W.—Surgeon.

Chesterfield and North Derbyshire Royal Hospital.—H.S.

Cheyne Hospital for Children, Cheyne-walk, Chelsea, S.W.—Hon. Surgeon for Diseases of the Throat, Nose, and Ear.

Derby, Derbyshire Royal Infirmary.—Hon. Asst. Physician.

Dumfries and Galloway Joint Sanatorium Board.—Asst. Med. Supt. £300.

Durham County Hospital.—H.S. £150.

Great Yarmouth General Hospital.—H.S. £140.

Grove Park Hospital, Lee, S.E.—Sen. Asst. M.O. £500.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—Cas. M.O. At rate of £100.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Asst. Physician.

Hove Borough, &c.—M.O.H. £1000.

Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.

Ilford Isolation Hospital.—Temp. Res. M.O. £350.

Ilford, King George Hospital.—Two Hon. Anæsthetists. Each £50

Jersey General Hospital and Poor-law Infirmary.—Visiting Physician and Radiologist.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £100.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, City of.—M.O. £1800.

Liverpool, Eye and Ear Infirmary.—H.S. to Ophth. Dept. £100.

London Hospital, E.—Asst. Phys. to Children's Dept.

London University.—Studentship in Physiology. £100.

Macclesfield, Cheshire County Mental Hospital.—Asst. M.O. £350.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Manchester, Royal Children's Hospital, Pendlebury.—Res. Surg. O. At rate of £125.

Manchester, Royal Infirmary.—H.S. for Central Branch, Roby-street. At rate of £100.

Manchester, St. Mary's Hospital.—H.S. for Whitworth Park Hospital. At rate of £50.

Middlesex County Council.—District M.O. and Public Vaccinator for Parish of Harefield. £45.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. Res. M.O., Asst. Cas. O. and Jun. Res. M.O. At rate of £140, £125, and £100 respectively.

Newcastle-upon-Tyne Education Committee.—Asst. School M.O. £500.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.

Northern Hospital, Winchmore-hill, N.—Asst. M.O. £350.

North-Western Fever Hospital, Lawn-road, Hampstead, N.W.—Two H.P.'s. Each at rate of £80.

Nottingham General Hospital.—H.S. At rate of £150.

Oldham, Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.

Pendleton, Hope Hospital.—Asst. Res. M.O. At rate of £250.

Plymouth, South Devon and East Cornwall Hospital.—Res. Surg. O. and H.S. At rate of £150 and £100 respectively.

Queen's Hospital for Children, Hackney-road, E.—H.P. At rate of £100. Also Cas. O. At rate of £100.

Radium Institute, Riding House-street, W.—H.S. At rate of £150.

Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.

Rotherham Hospital.—H.P. £180. Cas. H.S. £150.

Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. at rate of £150 and £100 respectively.

Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. and Asst. H.S. At rate of £150 and £100 respectively.

Royal Free Hospital, Gray's Inn-road, W.C.—Sen. Res. M.O. £150. Also Asst. Surgeon and Asst. Surgeon to Ear, Nose and Throat Dept.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. for Out-patient Dept. £150.

St. Bartholomew's Hospital, E.C.—Asst. Physician-Accoucheur.

St. Helens Hospital.—H.S. £200.

St. John's Hospital, Lewisham, S.E.—Res. H.S. At rate of £100.

St. Leonards Hospital, Hoxton-street, N.—Asst. M.O. £350.

Samaritan, Free Hospital for Women, Marylebone-rd.—H.S. At rate of £100.

Scunthorpe and District War Memorial Hospital.—Second Res. Surgeon. £150.

Southport General Infirmary.—Jun. H.S. £100.

Stockport Infirmary.—H.P. £175.

Sunderland, Durham County and Sunderland Eye Infirmary.—Two H.S.'s. Each £350.

Swansea General and Eye Hospital.—Cas. O. £200.

Taunton, Taunton and Somerset Hospital.—H.P. £100.

Wallasey Victoria Central Hospital.—Jun. H.S. At rate of £100.

Walsall General Hospital.—H.S. At rate of £150.

Walsall Manor Hospital.—Jun. Res. Asst. M.O. £150.

Warrington Infirmary and Dispensary.—Anæsthetist. £150.

West Bromwich, Hallam Hospital.—Res. H.S. £250.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Res. and Jun. Non-Res. H.S.'s. At rate of £150 and £100 respectively.

Wigan Infirmary.—H.S. At rate of £150.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Henley-in-Arden (Warwick).

NOTES, COMMENTS, AND ABSTRACTS

HOMER'S SURGEONS: MACHAON AND PODALIRIUS.

BY S. WOOD.

(From the Library, Royal College of Surgeons of England.)

PART II.*

Podalirius.

So far as we know, Podalirius, the younger son of Æsculapius, was also born at Tricca in Thessaly. References to his life and work are disappointingly few but there is something of romance by way of compensation, and he is of importance as being the ancestor, through Hypolochus, one of his sons, of the great Hippocrates. According to Arctinus [41] he was endowed with great precision of mind, with the power to recognise hidden diseases, and to cure chronic maladies. He it was who first perceived by his glittering eyes and depression of spirits the insanity of Ajax.

In the *Iliad* his name occurs twice only, while that of his brother, who was chiefly a surgeon, is mentioned 11 times. This circumstance may be explained by the fact that injuries sustained in battle would naturally come under the care of the surgeon rather than that of the physician. Quintus Smyrnæus [42] shows him as the possessor of a "kwick-kure" salve which healed wounds in a miraculous fashion:

. . . . Then their bruises and their scars
Did Podalirius tend with loving care
First presses he out black humours, then his hands
Deftly knit up the gashes, salves he laid,
Thereover, given him by his sire of old,
Such as had virtue in one day to heal
The deadliest hurts, yea, seeming-cureless wounds.
Straight was the smart assuaged, and healed the scars
Upon their brows and 'neath their clustering hair.

Podalirius took an active part as medical man and warrior in the Trojan war and helped to sack the kingdom of Priam. On his return from the expedition his vessel was cast by a tempest upon the Isle of Scyros,† where he was washed up safe and sound. He wandered alone in the peninsula of Caria until he became the guest of a shepherd, who, as soon as he learnt that his visitor was skilled in medicine, conducted him to King Damethus, whose daughter Syrna had fallen from the top of a house and lay seriously injured. The young princess was unconscious and motionless and was already regarded by her friends as dead, but the clever Podalirius bled her from both arms and had the happiness of recalling her to life.[43] Damethus, full of gratitude, gave his daughter to Podalirius in marriage, together with the peninsula of Caria, or the Chersonese as a wedding gift. Differing from the majority of writers Gordon [44] ascribes the girl's trouble to the "falling sickness" and says that in marrying her Podalirius was among the first, if not the first, medical practitioner to be conquered by a fair and interesting patient.

A Chersonese is a tract of land which is an island except where it is joined to the main by a narrow neck of land. The king's gift to Podalirius, according to Le Clerc [45] was not the Achaian peninsula called Polaponnesus lying between the Aegean and Ionian Seas, but the Thracian‡ between the Propontis and the Euxine Seas.

In the Carian Chersonese he founded the town of Syrna and likewise another which he called Bybassus, the name of the shepherd who succoured him after his shipwreck.[46]

The First Venesection.

The operation by Podalirius on the princess is said to be the first example of venesection performed as a curative measure, but unfortunately it is not very authentic. Etienne de Byzance, who reported the incident in the fifth century or 1600 years after the operation took place, does not say whence he derived his information. There is no certain knowledge of the origin of venesection, although an ancient tradition of the Egyptians seems to indicate that it was of their invention.[47] We know that it was practised long before Hippocrates, for in various places he speaks of it as a common operation in his time. Pliny,[48] in his usual manner, introduces a fable to account for the discovery of phlebotomy. "The hippopotamus," he says, "when too bulky by overfeeding goes to the reeds by the river and, choosing a stump that is very sharp, presses himself against it and wounds a vein in the thigh which is allowed to bleed till the body is relieved, after which the wound is covered with mud." Thus according to Pliny were the beneficial effects of bleeding first demonstrated to man, but the story cannot be credited by those who know the natural history of the animal.

Podalirius. (Reproduced from the title-page of John Woodall's "The Surgeon's Mate," London, 1639.)

Podalirius is said by Quintus Smyrnæus [49] to have cured Philoctetes of his lameness, and although the induction of the curative sleep appears to be more probably the work of the physician-brother, the successful treatment of this case is usually attributed to Machaon. Podalirius had several children, among them being the son Hypolochus from whom, as mentioned above, Hippocrates was descended. As is well known, the snake is frequently present in the early history of medicine and it is related that Alexander, an impostor, kept a very tame one, pretending it to be the son of Podalirius. Le Clerc [50] says this account is erroneous and that the quack called the snake Æsculapius and himself the son of Podalirius.

---

* Part I. appeared last week.

† There is much confusion regarding the geography of Podalirius. The present day Isle of Scyros is far from Caria, where he met the shepherd. Pausanius (Lib. 3, Ch. 26, p. 449) says positively that Scyros was opposite the Carian peninsula, from which the island depends. Sprengel considers Scyros to be identical with Nisyros and this opinion is supported by the position of Bybassus, the town founded by Podalirius, which was situated on the Cnidian peninsula, the only substantial prolongation of land on the Carian coast to fulfil the description of a chersonese.

‡ Le Clerc here seems to be in error. The projection of land of which he speaks between the sea of Marmora and the Black Sea has not the shape of a chersonese; moreover, it is on an opposite course from that which Podalirius would take homeward to Thessaly, and it is improbable that this part of the country would come within the sovereignty of King Damethus. The Chersonese Thracia of antiquity is the present Gallipoli, and for Podalirius to be wrecked here it is necessary to assume that he was so unskilful a mariner as to begin his voyage from Troy in a tempest.

Apollodorus [50a] writes that when Troy had been laid waste Podalirius and others left their ships in Ilium and journeyed by land to Colophon, where they buried Calchas the diviner, one of their number, who died heart-broken through wrangling with a better diviner than himself whom he met in Mopsus.

His Death and Burial.

Lycophron asserts that Podalirius was assassinated on the coast of Ausonia in the country of the Dauni who afterwards worshipped his memory. These people bathed in the river Althenus and listened while resting on the skins of animals to the infallible oracles of the god of medicine. He had a shrine at the foot of Mount Drium in Daunia, and because of this Lycophron said that he was buried in Italy, and for so saying was severely taken to task by his learned but crabbed commentator Tzetzes [51] who roundly accused him of lying.

Strabo [52] says that the tomb of Podalirius may be seen a hundred stadia from the sea in the country of the Dauni, the capital of which, Luceria, existed at his time in the Capitanata at the bottom of the Gulf of Manfredonia, and he adds that the waters of the river Althenus, by virtue of the presence of the tomb, were a sovereign remedy for the diseases of cattle.

According to another story Podalirius went to Delphi and inquired of the oracle where he should dwell. He was told to take up his abode in that city in which, if the sky fell, he would suffer no harm. So he settled in a place in the Carian Chersonese, which was surrounded by mountains that might be expected to prop up the sky in case it were to fall. Yet another story, followed by Lycophron, is that he went to Apulia in Italy, where he died and was buried, and that his spirit gave oracles in dreams to such as slept on sheepskins laid on his tomb.[53]

His name is commemorated in science by being applied to one of the subdivisions of the natural order of plants, Papilionaceae—namely, the Podalyriæ.[54] Rees,[55] the Cyclopædist, is surprised that Podalyrius should have been given a botanical association, overlooking the fact that he was learned in the properties of drugs of "pain-assuaging" power, which were certainly infusions of herbs, and that on the death of his brother he was found by Nestor seeking amongst his herbs for a deadly substance to destroy himself.

Diodorus of Sicily in his account of the brothers says that they lived and worked together in perfect harmony and acquired such a reputation among their companions that they were exempt from fighting and the fatigues of warfare. However, they did not avail themselves of this privilege, for, as we have seen, they took a leading part in the attacks on the Trojans and appeared to treat surgical cases as incidents which cropped up amidst their "valorous deeds."

They are said by Apollodorus [56] to have been among the suitors for the hand of the beautiful Helen of Troy, which appears to have been the fate of any man who had the misfortune to gaze upon her supernatural charms. The courage of her suitors must have been of a high order to enable them to woo a being of whom Marlowe in his "Faustus" exclaims,

> "Oh! thou art fairer than the evening air
> Clad in the beauty of a thousand stars!"

Portraits of the Brothers.

In addition to the reproductions in this paper the subjects of these notes appear in portraiture as follows: Daremberg [57] reproduces a plate showing Machaon dressing Menelaus's wound, the position of which bears little relation to Homer's text. The scene is also figured in Plate XV of a Greek manuscript published by Cardinal Mai,[57] but the artist has placed the wound just above the knee, whereas it should be in the region of the flank. T. Cades [59] reproduces a pâte de verre representing the same incident. Figure 37 of Daremberg's plate is a side view of the wounded Machaon and Nestor who is lifting the cup to drink the liquor prepared for them by Hecamede. These two figures also appear on a terra-cotta in the Musée du Louvre and in the British Museum, and are illustrated in the historical works of Panofka [60] and Winckelmann.[61] In his book on antique monuments Millen [62] gives a picture of two faces in profile which are said to represent Podalirius and Machaon. On the first head is a soldier's casque, and on the second a physician's cap.

There is a portrait of Machaon in the Van Kaathoven Collection in the Surgeon-General's Office of the United States Army, and a curious small engraving of Machaon, partly cut away by a careless bookbinder, appears on the title-page of Brumfel's "Catalogus illustrium Medicorum," 1529, in the Royal College of Surgeons' Library. Cabanès [63] has an illustration of Machaon and Nestor reproduced from Inghirami [64] in whose work Machaon appears at the healing of Philoctetes, and dressing the wound of Menelaus. Pausanius says that the Messenians had in the temple of Æsculapius amongst many great curiosities a sort of family piece of painting wherein was Æsculapius, his mother, and his two sons Machaon and Podalirius, drawn by Omphalion.[65] Pausanius also refers to the tomb of Machaon at Gerenia, which was a sanctuary where the sick were made whole. The inhabitants named the sacred place Rhodus, and here stood an image of Machaon in bronze, on the head of which was a wreath called in the local dialect "kiphos."

ASSOCIATION OF MATERNITY AND CHILD WELFARE CENTRES.

THE slight alteration in title of the society known since its foundation in 1911 as the Association of Infant Welfare and Maternity Centres is part of a new constitution rendered necessary by reorganisation of the Association's work consequent on the voluntary liquidation of the National League for Health, Maternity and Child Welfare, and adopted at last year's annual meeting. The report for 1930 records the affiliation of 28 new centres, including one in Rhodesia and some in India, and speaks of lively activity in the employment bureau, where 904 applicants were registered as compared with 689 in the previous year. The publications department was slightly less busy than in 1929, though its sales again numbered over 300,000 and proved a useful source of income. Two of the Association's most humane activities are the conduct of the Tired Mothers' Holiday Fund and of the Babies' Homes Department. During the year 25 mothers were helped to go for holidays, a grant up to £3 being made where a mother can arrange to be away for a fortnight, either going alone or taking one child. The John Madocks home for babies at Basing and the Arkley home for toddlers at High Barnet were constantly in demand, and many children had to be refused for lack of accommodation. Both these homes, as well as the babies' hotel at Clapham Park, act as training schools for nursery nurses, and the Association also helps in the administration of the Creagh Nursery Training School, which has established a high reputation for the standard of nurses sent out. In collaboration with the National Council for Maternity and Child Welfare statistics and other material were collected for the maternity and child welfare section of the museum of the London School of Hygiene and Tropical Medicine. The record is one of many-sided usefulness cramped by financial anxiety.

THE INSTITUTE OF RAY THERAPY.

THE Camden-road Institute was officially opened on March 13th of last year, and its first annual report shows that it is filling a real need. It has been open from 2 to 9 P.M. every weekday, except for a period of redecoration in December, and already 1450 patients have been seen, the average of new patients being 28 every month. The total number of attendances is over 40,000, as each patient receives on an average 27 treatments. The industrial depression of this winter reduced the number, as many patients were unable to afford even their fares and left their course of treatment incomplete. The Institute has paid its way on current expenditure, with the help of a number of approved societies and business firms; a canteen for patients, opened in May, has been self-supporting. An appeal for subscriptions and donations will, however, be necessary in the near future in order to pay off the capital expended. Patients are only received on a letter from their medical practitioner. The chief affections treated have been rheumatic and nervous conditions, debility, asthma, bronchitis, skin diseases, and children's ailments, but the numbers are not considered to be sufficient for the publication of statistical results. Of the 574 patients discharged by the medical director, 83·6 per cent. were fit or much improved, while 16·4 per cent. showed no signs of improvement. The patients include old-age pensioners, workers at an immense variety of trades, and children, for whom special arrangements have been made for treatment outside school hours. The Institute has been recognised by the Society of Apothecaries as a training centre in therapy for the biophysical assistants' examination.

DISEASE IN THE PRE-SCHOOL YEARS.

AT a meeting of the Society of Medical Officers of Health on April 17th, at which Prof H. Kerr (Newcastle-on-Tyne) took the chair, Dr. Ethel Cassie showed a chart, drawn up from her observation of cases in Birmingham, which recorded the incidence of such conditions as rickets, otorrhœa, enlarged tonsils, lung infections, and many others, in children grouped according to age, from 18 months to 5 years. With many of these conditions, notably with enlarged tonsils, defective teeth, orthopædic defects, lung infections other than chronic bronchitis, defective hearing, and squint, the percentage incidence rises steadily in the increasing age-groups, reaching a maximum between 4 and 5 years. With defective teeth the rise is from 2·3 per cent. in children under 2, to 52·3 per cent. in children between 4 and 5. Dr. Cassie emphasised the need for the education of parents in the better training and management of children during the early years, education which she believes should be given at the child welfare centres; she appears to be able to secure the attendance of the child up to school age at Birmingham, but neither she nor Dr. G. C. M. M'Gonigle (Stockton-on-Tees), who spoke after her, outlined a constructive scheme by which the pre-school child could receive regular medical supervision all over the country. Dr. M'Gonigle attacked another aspect of the problem; he pointed out that it was at present exceptional to find a physically perfect child of 5, a fact which indicated some radical fault in the nurture of young children. In his opinion the initial error is far more often nutritional than environmental; the frequency with which the diet of the expectant mother and the young child is deficient in vitamin content, especially A and D, is responsible, he considers, for the high incidence of dental disease, and he advocates the administration of cod-liver oil to pregnant women as a routine.

In this view he is opposed by Dr. Sim Wallace (London) who quoted the high incidence of dental disease in Hawaii, where sunshine is abundant and rickets said to be rare. Dr. R. M. F. Picken (Cardiff) considers that any scheme which is to include the care of the child between 1 and 5 should make it possible for the same doctor to attend him from infancy to the end of school life, an arrangement which calls for some ingenuity in the organiser, but which both he and Dr. Agnes Nicoll (Willesden) have attempted. The difficulty is to persuade the parents to bring their children to the clinics once they have passed the dangers of infancy; Dr. John Macmillan (Woolwich) has managed to secure the attendance of a certain number by sending the health visitor round on the day before the clinic to obtain promises of attendance. At first out of 30 promises, 7 mothers would attend, but now, after eight months, it is common to secure 20 attendances from 24 acceptances, which suggests that the mothers are as educable in the care of their pre-school children as they were in the care of infants when the welfare centres were first started. Dr. E. H. T. Nash (Hounslow) believes that the best way to provide supervision for these children is to extend the nursery school system, under which they will receive not only medical attention, but adequate nurture, and such psychological training and guidance as is now regarded as essential in the early years.

OPERATIVE TREATMENT OF PILES.

REFERRING to an annotation on his modified clamp-and-cautery method of treating piles (THE LANCET, March 14th, p. 598), Dr. David Warshaw (Albany, N.Y.) writes: "One important point seems to have been *misunderstood by your abstract* editor—namely, his criticism that there is no assurance of protection of the deeper tissues against injury by the technique I described. Careful perusal of the article will reveal the fact that monopolar current is used. This current cannot penetrate beyond the clamp, as the clamp itself takes up any excess current which the operator may use."

We regret having given a wrong impression of Dr. Warshaw's method. The mistake arose from a misreading of the word diathermy. In this country all diathermy machines produce a bipolar current which has considerable penetrating powers. It appears that the machine which Dr. Warshaw employs is monopolar and produces a local spark with no power to penetrate the tissues. *In this country* "high-frequency" rather than "diathermy" would be the term used in describing the method.

NASAL DISINFECTION.

Dr. William Stanwell (New Milton, Hants) suggests the disinfection of contacts and carriers of cerebrospinal fever by a method he has found useful in dealing with whooping-cough. An ointment is made by *melting* together vaseline, 1 lb.; menthol, 2 *drachms*; *medical* izal, 4 drachms. Two drachms of this ointment are packed with a spatula into the nostrils of a recumbent patient whose head is thrown well back, and who remains in this position until the ointment has melted and reached every part of the nasal cavity. This treatment he has found to cut short an attack of whooping-cough and to do away almost entirely with the violent paroxysms of cough.

NEW PREPARATIONS.

ABRODIL (Bayer Products, Ltd., 19, St. Dunstan's-hill, London, E.C.) has already been described in the columns of THE LANCET in reviewing a paper on excretion urography by Drs. H. Bronner and J. Schueller, of Cologne. It is the sodium salt of mono-iodo-methane-sulphonic acid. After intravenous injection of large doses no inorganic iodine is found in the urine of rats, cats, and dogs, and this shows that it is excreted by the kidneys without the splitting off of iodine. It is also strongly diuretic. The diuresis is mainly in the first half hour, and the best pictures for the purposes of pyelography are therefore obtained during that period, the ideal time being usually 15 to 20 minutes after injection. Drs. Bronner and Schueller have tested abrodil as a medium for retrograde pyelography, and recommend for this purpose a 15 to 20 per cent. solution. The fact that abrodil is compatible with oxycyanide of mercury allows of its being used in conjunction with this antiseptic. The danger of sepsis is thereby diminished, and the surgeon is relieved of one of the anxieties uppermost in his mind when undertaking retrograde pyelography.

SOMNOSAL (Messrs. H. R. Napp, Ltd., 3 and 4, Clement's-inn, London, W.C.) is a combination of a brom-iso-valerianyl urea (grs. 5) with dimethyl-amido-phenyldimethyl-iso-pyrazolon (grs. 2·5). The preparation dissolves in alcohol and the usual solvents but is only partly soluble in water. It is put on the market as a trustworthy sedative of negligible toxicity, whose employment is unaccompanied by secondary symptoms or habit forming. A considerable amount of medical evidence is adduced of the utility of the preparation, which is free from barbiturates and opiates.

From the same firm we have received a sample of ANOTAL, a combination of phenyl-cinchoninic acid and ethyl-urethane. The manufacturers claim satisfactory results for the new preparation in the treatment of rheumatism, gout, and local inflammations, the analgesic action being rapid, while medical evidence is adduced that it is well tolerated by patients who suffer from no gastric disturbance or cardiac depression if the suggested dosage is observed. Anotal is put up in phials of 30 tablets, and in bottles of 300, the dosage being one or two tablets, to be taken in cold water thrice daily, according to medical direction.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, April 27th.—8 P.M., ODONTOLOGY. Paper. Mr. Wilson Charles: Full Denture Prosthesis. 5 P.M., MEDICINE. Short Papers: Dr. W. S. C. Copeman: Treatment of Chronic Arthritis by Blood Transfusion. Dr. Donald Hall: Two Unusual Electrocardiograms. Dr. Donald Hunter: Hæmatogenous Myelomatosis. Dr. M. Schwartzman: Skeletal Muscular Extract in the Treatment of Vascular Diseases. Dr. D. C. Wilson: Osteomalacia with Cinematographic film.

FRIDAY, May 1st.—10.30 A.M., OTOLOGY (Cases at 9.30 A.M.). Annual General Meeting. Papers. Dr. Schmaltz (Germany): The Physical Phenomena Occurring in the Semicircular Canals during Rotatory and Thermic Stimulation. Dr. H. W. Barber: Eruptions Involving the External Auditory Meatus. Discussion: Non-malignant Diseases of the External Ear and Auditory Meatus. Cases and specimens will be shown. 5 P.M., LARYNGOLOGY (Cases at 4 P.M.). Annual General Meeting. Communication. Prof. Georges Portmann: A Big Tumour of the Deep Regions of the Face removed by Operation with Cure. Discussion: Obstruction at the Upper End of the Œsophagus (excluding Pharyngeal Diverticula). Openers: Dr. A. Brown Kelly and Dr. D. R. Paterson. 8.30 P.M., ANÆSTHETICS. Annual General Meeting. Election of Officers and Council. A Clinical Evening will follow.

EUGENICS SOCIETY.

TUESDAY, April 28th.—5.30 P.M. (at the Rooms of the Linnean Society, Burlington House, London, W.), Dr. A. J. Lewis: Genetic Problems in Psychiatry.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, May 1st.—8.30 P.M. (at West London Hospital, Hammersmith): Discussion on Cholecystitis. (Opener: Dr. Maurice Shaw.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, April 27th, to SATURDAY, May 2nd.—HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C. Special post-graduate course in Diseases of Children occupying mornings only with lectures, demonstrations and operations.—INFANTS HOSPITAL, Vincent-square, S.W.—Special afternoon course in diseases of infants. Demonstrations, lectures, and special visits.—MAUDSLEY HOSPITAL, Denmark-hill, S.E. An afternoon course of lectures in Psychological Medicine. Clinical instruction in the Hospital.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C. All-day Course in Diseases of the Ear, Nose, and Throat, lectures, demonstrations, &c.—Further particulars from the Fellowship of Medicine.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, University-street, Gower-street, W.C.

WEDNESDAY, April 29th, and the following THURSDAY and FRIDAY.—5.30 P.M., Prof. Otfrid Förster (Univ. of Breslau): Neurology.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, Gower-street, W.C.

TUESDAY, April 28th, and following WEDNESDAY, THURSDAY, and FRIDAY.—5 P.M., Prof. F. A. E. Crew: Laws of Inheritance.

HAMPSTEAD GENERAL AND NORTH-WEST LONDON HOSPITAL.

WEDNESDAY, April 29th.—4 P.M., Dr. Hubert Oddy: Treatment of Gastric Ulcer.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, April 28th.—4.15 P.M., Mr. J. P. Buckley: Some Problems of Early Diagnosis.

FRIDAY, May 1st.—4.15 P.M., Mr. P. R. Wrigley: Demonstration of Surgical Cases.

MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL, Elizabeth-street, Manchester.

WEDNESDAY, April 29th.—4.30 P.M., Dr. W. Brockbank: The Medical Treatment of Asthma.

UNIVERSITY OF BIRMINGHAM.

TUESDAY, April 28th.—3.30 P.M. (at the General Hospital), Mr. S. Barling: Demonstration of Surgical Cases.

Births, Marriages, and Deaths

BIRTHS.

DE BARGUE HUBERT.—On April 18th, at Grosvenor-road, S.W., the wife of Dr. W. de Bargue Hubert, of a daughter.

MARRIAGES.

AITKEN—WEST.—On April 14th, at Macduff, Banffshire, Alan Boultbee Aitken, of Creigiau, Cardiff, to Dr. Gladys Mary West.

FAIRLEY—ROSSER.—On April 17th, at Saint Augustine's-road, Edgbaston, James Fairley, B.Ch. Camb., to Margaret C. Rosser, M.B., Ch.B.

HOBBES—CAMERON.—On April 16th, at St. Mary's, Selly Oak, Theodore H. Hobbes, M.B., B.S., to Janet Seaton Cameron, M.B., Ch.B.

DEATHS.

ACLAND.—On April 16th, at Bryanston-square, London, W., Theodore Dyke Acland, M.D. Oxf., F.R.C.P., aged 79.

CHRISTIE.—On April 14th, 1931, at 1, Albyn-terrace, Aberdeen, John F. Christie, M.A., M.B., C.M., F.R.C.P.E.

DEAN.—On April 14th, at Abinger-road, Bedford Park, Henry Percy Dean, F.R.C.S., M.S., M.B., B.Sc., aged 66.

HARRIS.—On April 16th, Major-General G. F. A. Harris, C.S.I., M.D., F.R.C.P., I.M.S., in his 76th year.

SMITH.—On April 18th, at Cobden-crescent, Edinburgh, James Lorrain Smith, F.R.S., Professor of Pathology, University of Edinburgh.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

HARROW HOSPITAL.—Last year each in-patient cost an average of £3 5s. 9d. per week, as against £2 12s. in the preceding year. The average total costs of each patient—£7 10s.—includes 844 out-patients. The hospital was closed for six weeks last summer for alterations necessitated by the extension schemes.

ADDRESSES AND ORIGINAL ARTICLES

THE SPLEEN: ITS STRUCTURE, FUNCTIONS, AND DISEASES.

By J. W. McNee, D.S.O., M.D., D.Sc. Glasg., F.R.C.P. Lond.,
ASSOCIATE PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON.

LECTURE I.

The human spleen is of considerable size, easily accessible, and, when enlarged, easily palpable through the abdominal wall. Thus it is not surprising to find far back in the history of medicine numerous records of curious beliefs and speculations about splenic function which were the outcome of the attention paid to this organ by early writers. Yet real knowledge of its intimate structure has accumulated amazingly slowly in comparison with that of other organs of the body. One good reason for this is no doubt the fact, established from the earliest times, that the spleen has not any function absolutely essential for life, and so some less fundamental reasons for its presence in the body had to be discovered.

Early Physiology.

The very earliest views concerning splenic function are not easy to trace, and I am greatly indebted to various friends interested in the history of medicine, and particularly to Dr. Charles Singer, for help in this connexion. Interesting accounts are also contained in the book of Charles Gray (1854), and in the recent review by Krumbhaar (1926).

The spleen was described by Hippocrates in his treatise "De Carnibus," and he states that its function is to draw the watery part of the food from the stomach. Aristotle also described the organ and suggested a somewhat similar function. Nothing further of note emerges until we come to Galen (A.D. 130–200), who rightly termed the spleen an organ "full of mystery." Galen's physiology was built around the hypothesis of the four humours—blood, phlegm, choler, and melancholy. Gradually each humour became associated with a corresponding organ of the body, generally the brain with phlegm, the heart with blood, the liver with choler, and the spleen with "black bile" or melancholy. To fit in with this old physiology a spurious anatomy was invented, and an imaginary duct was traced from spleen to stomach, for the excretion of "black bile." Excess of one or other of the four humours was supposed to produce a phlegmatic, sanguine, choleric, or melancholic temperament, and deficiency the reverse. These ancient views of Galen persisted, and were believed almost universally for more than a thousand years, and Robin in his interesting book, "The Old Physiology in English Literature," states that at the University of Cambridge, in the fourteenth century, medical students were still compelled to attend two full courses of lectures on "Galen's Commentaries upon Hippocrates." The ideas expressed in the Galenic physiology have provided many striking passages for the classical writers of English poetry and prose (see Robin), and even now we may speak of "venting our spleen." Some of the hypotheses known to Galen were also described, but in far less accurate form (as Dr. Singer has assured me) by Pliny (A.D. 23–79). The first translation of Pliny into English is a remarkable volume, published by Philemon Holland in 1601. It is a rare book, but I have seen Dr. Singer's copy, and it is both interesting and amusing. Pliny's writings are of particular interest to us, in that he makes the first definite reference that I have been able to trace, to extirpation of the spleen in runners.

Here is the passage, copied from Philemon Holland's book:—

> "This member hath a proprietie by itselfe sometimes, To hinder a mans running: whereupon professed runners in the race that bee troubled with the splene, have a devise to burne and wast it with an hot yron. And no marveile: for why? they say that the splene may be taken out of the bodie by way of incision, and yet the creature live neverthelesse: but if it be man or woman that is thus cut for the Splene, hee or shee looseth their laughing by the meanes. For sure it is, that untemperate laughers have alwaies *great splenes.*"

As regards the last part of the quotation it will be noticed that Pliny is a little muddled, as is indeed often the case, for on the hypothesis of the four humours it is the melancholics who should have great spleens, and not the laughers. There is a well-known tradition, and perhaps even written evidence, although I have been unable to discover it even after much search, that the spleens of Greek runners even in the earliest times were removed to increase their speed and endurance. Gurlt, in his monumental "History of Surgery," gives no clue to the origin of this tradition, and apart from giving the reference to Pliny, just described, he merely mentions that the subject is referred to in the ancient Hebrew Talmud.

So much for the earliest views concerning splenic function—an interesting story on which a whole series of lectures could be based. After Galen there is little speculative writing to detain us until the seventeenth century, after Francis Bacon had laid the foundations of the renaissance of science.

SUCCESSFUL SPLENECTOMY.

Experiments began, and the first recorded splenectomies were carried out in dogs by Zambeccari in 1680. Malpighi, the discoverer of the lymph follicles in the spleen, had earlier (1665) ligated the splenic vessels in dogs without apparently injuring their health, and later he also performed splenectomy successfully in the same animals. Similar experiments were done by many others, especially in England, and the facts were well known to Stukeley in 1722. Various symptoms, not harmful to health, such as increased frequency of micturition and voracious appetite, were described as sequels to the operation.

The first operation for removal of the human spleen is said to have been performed by Zaccarelli in 1549. Pernet, Moynihan, and Krumbhaar all refer to this case in their accounts of the history of splenectomy. The case is recorded with great circumstantial detail by Fiorovanti (1518–88), who, however, is described by Stukeley as "a famous empiric, and the first mountebank in Europe." The patient was a young woman of 24, named Marulla, wife of a captain, and her spleen was so large as practically to fill the abdomen. The services of Zaccarelli, of Naples, were enlisted, and he successfully removed the spleen, recovery being complete in 24 days. The organ is said to have weighed 32 oz. after removal from the body, which tallies ill with the previous clinical description of its size.

---

* The Lettsomian lectures delivered before the Medical Society of London on Feb. 16th and 25th, and March 4th 1931.

Another early case (1676) is of especial interest, if authentic, since it may have been the first human splenectomy performed in this country. It is recorded by Dr. Timothy Clarke (physician to Charles II., and a friend of Pepys) as related to him by a Dr. Turbervile. Here again the reputed facts of the case are given in considerable detail. The patient was a Somerset man, William Panier, who attempted suicide by stabbing himself in the left side with a butcher's knife, so that spleen, omentum, and intestines projected. Three days later a surgeon replaced the intestines, and cut away the spleen and omentum. Recovery to perfect health ensued, and the man was known to be alive years afterwards. Various other curious cases of removal of the spleen after knife wounds are referred to in the literature (Spencer, 1920), and it seems probable that in times of war opportunities for the operation would be offered from time to time. It must be remembered, however, that facilities for publishing such cases in print were extremely limited until 100 years ago.

In more recent times there is the well-known case of Spencer Wells (1866), which is probably one of the first English cases in which the abdomen was deliberately opened and the spleen at once removed, but the patient died one week later. With the advent of Listerian principles of surgery splenectomy was soon frequently performed, but at first the death-rate from the operation was high.

STUDIES OF FUNCTION.

We may return now to a consideration of how real knowledge of the structure and functions of the spleen was acquired, after the influence of Galen and his teaching had waned. We may fittingly commence with the observations of the famous Italian anatomist Malpighi (1665), who not only described the lymph follicles but also noted in dogs that the trabeculæ were muscular and capable of contraction. As to function he considered that the organ was essentially a gland, and although it had no ducts he suggested that the large veins and spongy structure of the organ would adequately suffice for glandular excretion. His final conclusions, however, were quite definite: "What therefore is to be thought of this artificial bowel, I am perfectly ignorant." In 1722, William Stukeley gave his Goulstonian lecture to the Royal College of Physicians of London, On the Spleen: Its Description and History, Use and Diseases. The lecture was published for the author in 1723, and is a most beautiful book, illustrated by his own fine drawings. Stukeley's work is remarkable both for its style and for the ideas expressed, some of which, as shall be seen, were far in advance of his own times. Some of his introductory remarks (page 2) are delightful.

> "The uses of the apparatus [i.e., the contents of the abdominal cavity] are by the industry of the Curious pretty manifest, except that of the Spleen; which yet has not fail'd to be a subject of enquiry in all ages, and has rack'd the brains of physicians, as well as the bowels of their patients. . . . But still, what formerly was the seat of joy [here Stukeley follows Pliny] is become a topic of grief to the moderns, since our improvements have presented us with no other than a negative knowledge therein; and in the main we are forc'd to own our ignorance of nature's intention in forming the curious organ of the spleen."

Stukeley's own views of splenic function are, however, set forth with the utmost clearness, and are of great historic interest in view of recent developments in splenic physiology (Barcroft, Binet, and others). He recognised that this spongy organ could, when filled with arterial blood, "at pleasure upon its contraction" empty itself again. He asserted that the organ served to maintain the balance of the circulation, acting as a sort of diverticulum or safety valve to the general systemic circulation. Some of his remarks are for us even nowadays so apt, that he may be allowed briefly to speak for himself in some sentences from page 50 of his book.

> "I take it for granted that in common way of living we make more blood than is just necessary for the occasions of life; and without this provision, we should be subject to a thousand inconveniences."
>
> "She would be a very imprudent and improvident mother, or rather stepmother, that was so niggardly as only to take care of supplies the moment we want it. So complicated a machine, liable to external injuries and internal disorders, must have a reasonable *overplus*, a stock in hand to be employed whenever there is occasion, and for fear a regular supply should be procrastinated."
>
> "Even regular exercise and muscular motion . . . demand a considerable plenitude of juices; and if there was not more than enough, we should be continually fainting."
>
> "Therefore this so necessary a surcharge of blood, I suppose so regulated by the spleen, as that no inconveniences arise from it." . . .

Stukeley's views were supported in the main by Lieutaud (1738, 1742) and Hodgkin (1832).

If Stukeley's book may be regarded as the "classic" on the spleen in the eighteenth century, then the book of Henry Gray, "On the Structure and Use of the Spleen," published in 1854, holds the same position in the next century. He gives a remarkably full historical account, on which I have freely drawn for these lectures, and also a whole series of interesting observations made by himself. He unfortunately failed, in his experiments, to prove the contractile power of the spleen, and so he gives the organ a much more passive rôle as a regulator of blood-supply than did his predecessor Stukeley.

A contemporary of Henry Gray, the comparative anatomist Kölliker (1849), first noticed the disintegration of red blood corpuscles within the cells of the spleen. This fact was soon amply confirmed by other observers and formed, until very recent years, the basis of the sole function attributed to the spleen in subsequent text-books.

Structure of the Spleen.

It has been convenient to describe the early history of our knowledge of splenic function without much reference to structure, since, if we except Malpighi's discovery of the lymph follicles, little was known except the gross anatomy of the spleen, until the rapid development of microscopic and histological technique in the middle of last century.

We may now, however, turn definitely to the problems of splenic structure, and since my object is to lead up to a consideration of the various forms of splenic disease met with in human beings, I shall confine myself to points in structure which may be important in that connexion. Full reviews of the modern development of our knowledge have been given by Tait and Cashin (1925), and by Hueck (1928). It is seen that most of the important papers date from the middle of last century, and that there is scarcely any agreement among them on fundamental points. It is also obvious that in recent times much of the older work, and its possible significance, has been completely forgotten. It has disappeared, at any rate, from all except some of the largest text-books of histology, and generally the descriptions given of the finer histology of the spleen in student's text-books are very poor and meagre. As soon as I began to be interested in diseases of the spleen, I naturally read the best available accounts of splenic histology, but the extreme divergences of opinion was an unexpected obstacle. Since, however, comparative studies of the structure of the liver lobule in different animals had greatly helped me in the understanding of hepatic disease, I determined to apply the same method to the spleen. In this work I was fortunate in having the coöperation of M. F. Cashin, who had already published work with Tait on the structure of the spleen. I may say at once that this comparative study of the spleens of animals has been of the greatest help in elucidating some of the problems of the complex human spleen. Our observations are given in detail elsewhere, and it should be stated that Gray, Whiting, Magnam, and others have made similar observations in the past, but not since improvements in histological technique, and especially not since recent developments in splenic physiology have been known to us. Reference should also be made here to the careful work of Mills (1927) on the spleen of the skate, and to the recent (unpublished) work of Basin, in Prof. J. P. Hill's laboratory at University College, on the spleen of echidna.

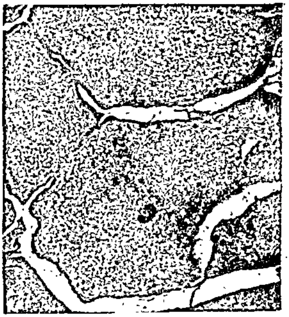
IMPORTANT ANATOMICAL FEATURES.

The following points concerning the structure of the spleen are important for the interpretation of the pathology of human splenic disease. Some of them have been known for many years; others were known but forgotten, and have been rediscovered anew; a few have only been lately recognised.

The spleen of all vertebrates is covered, below the peritoneal coat, by a fibro-elastic *tunica propria* which contains abundant muscle-fibres in some animals, such as the cat and the dog, which have been the subjects of many experiments concerning splenic contraction. In man, however, the muscle tissue of the spleen is chiefly confined to the splenic *trabeculæ*, structures which are not found in all vertebrates, being entirely absent from the fishes. These trabeculæ are definitely muscular, and arise both from the covering tunica propria and from the sheaths of the main blood-vessels. They are obviously of critical importance in relation to the contractility of the organ. The *reticulum* or *reticular network* is a structure often misunderstood, as Tait has pointed out, but it is a most important element in the structure of the spleen. It was first described by Tigri (1847) and again by Billroth (1857), but the name reticulum was first applied by Mall in 1890 to describe the peculiar meshwork in the spleen which, by special microchemical methods, he showed was different from the fibres both of white-fibrous and of yellow-elastic tissue. It has been held by others, however, that such a sharp distinction is not justifiable (R. A. Young, 1892). Ranvier (1891) first described the large multipolar cells lying on the reticular network of the spleen, and these cells, together with large amœbic phagocytic cells first observed by Ponfick (1869), constitute along with the reticulum the essential structures of the spleen-pulp. These cells are now included as an important part of the reticulo-endothelial system (Aschoff). The *Malpighian corpuscles* (Malpighi, 1669) are simply aggregations of lymphocytes, surrounded by a rather denser zone of reticulum than elsewhere. They are to be regarded simply as tiny lymph glands within the spleen, and they behave quite independently of the remainder of the splenic tissue in most human diseases. In our comparative study of the spleens of animals they were found to be inconstant. Fishes have none at all, but they occur in reptilia and all other animals higher in the scale. Some birds' spleens show them to be present, but in others they are absent. In mammals they are always more prominent in the young than in the old, and this is explained by the work of Gross, referred to later on.

The *lobularity of the spleen* is, I believe, a most important fact to take note of, and one which affects many pathological processes. All spleens are essentially lobular in structure, but this has often been forgotten in studies confined to the complex spleens of man and the higher animals. Yet a tendency to lobularity can still be made out by special methods of staining even in the adult human spleen, and, as is noted later, definitely lobulated human spleens are not altogether rare. In fishes, and even more remarkably in reptilia, lobulation is distinct. In one lizard examined (*Veranus niloticus*) the subdivision into lobules is complete, each separate lobule being supplied by its own end-artery. In the spleen of a crocodile Cashin and I calculated that there were probably about three hundred separate lobules.

FIG. 1.



Lacertilia. *Veranus niloticus* (monitor). The lobular structure of the spleen is shown; each lobule has a central artery, and the blood is confined in venous sinuses (low power).

The *vascular system of the spleen* is obviously of critical importance for the development of all pathological processes, but the study of this system has always presented great difficulties and has led to much divergence of opinion which is not yet reconciled. The main blood-supply to the spleen, and the collateral circulation, has an importance both for the surgeon and the pathologist. It has been well studied by Valdoni (1929), an Italian surgeon, with the help of opaque vascular injections and X rays. The splenic artery in man is remarkable for its large size in proportion to the bulk of the organ. As a rule it is a single vessel, breaking up close to the hilum into a number of branches, but occasionally the branching takes place at some distance before reaching the hilum, causing surgical difficulties in an operation for splenectomy. This latter distribution of the branches of the splenic artery is the normal state in many animals. The main branches of the splenic artery within the spleen are tortuous and spring-like; they divide abundantly until, finally, each branch bifurcates to form two slender arterioles named *penicilli* by Ruysch (1696). These penicilli, as was first strongly emphasised by Cohnheim (1867), are end-arteries, and do not anastomose. An important part of the internal vascular arrangement of the spleen is the so-called *ellipsoid*, a structure formerly well known to histologists, but for a long time almost forgotten. The structure and significance of the ellipsoid has been very fully investigated by Tait and Cashin, and the history of its discovery has already been fully described by myself elsewhere. These peculiar structures were first noted by Billroth (1857), and named "kapillar-hülsen" by Schweigger-Seidel (1863), or "ampullæ" by Thoma (1895). They consist essentially of swellings or condensations

Another early case (1676) is of especial interest, if authentic, since it may have been the first human splenectomy performed in this country. It is recorded by Dr. Timothy Clarke (physician to Charles II., and a friend of Pepys) as related to him by a Dr. Turbervile. Here again the reputed facts of the case are given in considerable detail. The patient was a Somerset man, William Panier, who attempted suicide by stabbing himself in the left side with a butcher's knife, so that spleen, omentum, and intestines projected. Three days later a surgeon replaced the intestines, and cut away the spleen and omentum. Recovery to perfect health ensued, and the man was known to be alive years afterwards. Various other curious cases of removal of the spleen after knife wounds are referred to in the literature (Spencer, 1920), and it seems probable that in times of war opportunities for the operation would be offered from time to time. It must be remembered, however, that facilities for publishing such cases in print were extremely limited until 100 years ago.

In more recent times there is the well-known case of Spencer Wells (1866), which is probably one of the first English cases in which the abdomen was deliberately opened and the spleen at once removed, but the patient died one week later. With the advent of Listerian principles of surgery splenectomy was soon frequently performed, but at first the death-rate from the operation was high.

STUDIES OF FUNCTION.

We may return now to a consideration of how real knowledge of the structure and functions of the spleen was acquired, after the influence of Galen and his teaching had waned. We may fittingly commence with the observations of the famous Italian anatomist Malpighi (1665), who not only described the lymph follicles but also noted in dogs that the trabeculæ were muscular and capable of contraction. As to function he considered that the organ was essentially a gland, and although it had no ducts he suggested that the large veins and spongy structure of the organ would adequately suffice for glandular excretion. His final conclusions, however, were quite definite: "What therefore is to be thought of this artificial bowel, I am perfectly ignorant." In 1722, William Stukeley gave his Goulstonian lecture to the Royal College of Physicians of London, On the Spleen: Its Description and History, Use and Diseases. The lecture was published for the author in 1723, and is a most beautiful book, illustrated by his own fine drawings. Stukeley's work is remarkable both for its style and for the ideas expressed, some of which, as shall be seen, were far in advance of his own times. Some of his introductory remarks (page 2) are delightful.

> "The uses of the apparatus [i.e., the contents of the abdominal cavity] are by the industry of the Curious pretty manifest, except that of the Spleen; which yet has not fail'd to be a subject of enquiry in all ages, and has rack'd the brains of physicians, as well as the bowels of their patients. . . . But still, what formerly was the seat of joy [here Stukeley follows Pliny] is become a topic of grief to the moderns, since our improvements have presented us with no other than a negative knowledge therein; and in the main we are forc'd to own our ignorance of nature's intention in forming the curious organ of the spleen."

Stukeley's own views of splenic function are, however, set forth with the utmost clearness, and are of great historic interest in view of recent developments in splenic physiology (Barcroft, Binet, and others). He recognised that this spongy organ could, when filled with arterial blood, "at pleasure upon its contraction" empty itself again. He asserted that the organ served to maintain the balance of the circulation, acting as a sort of diverticulum or safety valve to the general systemic circulation. Some of his remarks are for us even nowadays so apt, that he may be allowed briefly to speak for himself in some sentences from page 50 of his book.

> "I take it for granted that in common way of living we make more blood than is just necessary for the occasions of life; and without this provision, we should be subject to a thousand inconveniences."
>
> "She would be a very imprudent and improvident mother, or rather stepmother, that was so niggardly as only to take care of supplies the moment we want it. So complicated a machine, liable to external injuries and internal disorders, must have a reasonable *overplus*, a stock in hand to be employed whenever there is occasion, and for fear a regular supply should be procrastinated."
>
> "Even regular exercise and muscular motion . . . demand a considerable plenitude of juices; and if there was not more than enough, we should be continually fainting."
>
> "Therefore this so necessary a surcharge of blood, I suppose so regulated by the spleen, as that no inconveniences arise from it." . . .

Stukeley's views were supported in the main by Lieutaud (1738, 1742) and Hodgkin (1832).

If Stukeley's book may be regarded as the "classic" on the spleen in the eighteenth century, then the book of Henry Gray, "On the Structure and Use of the Spleen," published in 1854, holds the same position in the next century. He gives a remarkably full historical account, on which I have freely drawn for these lectures, and also a whole series of interesting observations made by himself. He unfortunately failed, in his experiments, to prove the contractile power of the spleen, and so he gives the organ a much more passive rôle as a regulator of blood-supply than did his predecessor Stukeley.

A contemporary of Henry Gray, the comparative anatomist Kölliker (1849), first noticed the disintegration of red blood corpuscles within the cells of the spleen. This fact was soon amply confirmed by other observers and formed, until very recent years, the basis of the sole function attributed to the spleen in subsequent text-books.

Structure of the Spleen.

It has been convenient to describe the early history of our knowledge of splenic function without much reference to structure, since, if we except Malpighi's discovery of the lymph follicles, little was known except the gross anatomy of the spleen, until the rapid development of microscopic and histological technique in the middle of last century.

We may now, however, turn definitely to the problems of splenic structure, and since my object is to lead up to a consideration of the various forms of splenic disease met with in human beings, I shall confine myself to points in structure which may be important in that connexion. Full reviews of the modern development of our knowledge have been given by Tait and Cashin (1925), and by Hueck (1928). It is seen that most of the important papers date from the middle of last century, and that there is scarcely any agreement among them on fundamental points. It is also obvious that in recent times much of the older work, and its possible significance, has been completely forgotten. It has disappeared, at any rate, from all except some of the largest text-books of histology, and generally the descriptions given of the finer histology of the spleen in student's text-books are very poor and meagre. As soon as I began to be interested in diseases of the spleen, I naturally read the best available accounts of splenic histology, but the extreme divergences of opinion was an unexpected obstacle. Since, however, comparative studies of the structure of the liver lobule in different animals had greatly helped me in clusions because of technical difficulties with the small fragile vessels. It seems almost impossible to hope to solve the problem by purely histological methods in the complex spleen of man or the higher animals, and there are still supporters of each of the three hypotheses just mentioned. Help has come, however, from the physiological researches of Barcroft and his colleagues on splenic function, and particularly from experiments in which animals were poisoned with carbon monoxide. In these animals it was found that the blood in the spleen pulp remained free from the poison until the spleen contracted after exercise, when the blood in the pulp immediately contained the gas in the same concentration as that in the general circulation. This at once suggested a form of "two-way" or alternative circulation in the mammalian spleen, part of blood passing straight through and part being diverted into the pulp. What is the mechanism in the spleen by means of which such a double circulation is possible? I believe that Barcroft's work, together with the observations and experiments which I shall now describe, suggest strongly the essential structures involved.

EXPERIMENTAL OBSERVATIONS.

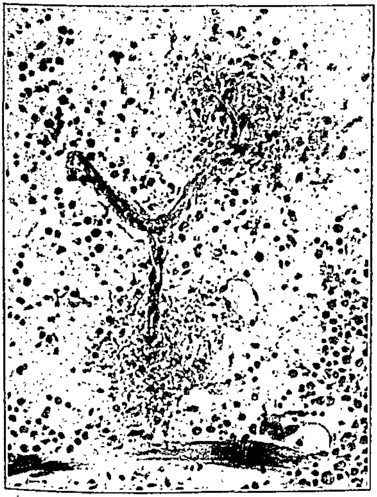
Cashin and I, by direct histological examination in several species of animals, were able to verify the earlier opinion of Whiting (1897), that the small splenic arterioles, after passing through the ellipsoids, open directly into blood-sinuses. We also easily confirmed the fact, as some of the microphotographs show, that channels or potential channels, in some animals lined by endothelium, penetrate the walls of the ellipsoids to end in the pulp. A series of experiments was also carried out in cats, in order to obtain support if possible for the above observations. Yeast-cells were grown in culture to approximately the size of the animals' red corpuscles, and injections of these cells were then made into the splenic artery of the living animal under differing conditions. In the first experiments the spleen, before the termination of the injection, was simply clamped off and fixed immediately by multiple subcapsular injections of formalin. In the second experiments the living spleen was kept firmly contracted by electrical stimulation of the nerves during the whole period of injection before it was clamped off and fixed with formalin. In the first experiments the yeast-cells were easily recognisable, by their different staining reaction from blood-cells, both in the blood-vessels and in the pulp. In the second, the yeast-cells were confined to the blood-vessels and blood sinuses, and absent from the pulp.

Further, in direct observations of the thin edge of a mouse's spleen, examined with a dissecting microscope and very powerful light, erythrocytes could be seen lying stationary in the pulp while blood was pumping freely through the adjacent arterioles into sinuses, and then emerging by the veins.

These simple experiments, together with those of Barcroft, undertaken for quite another purpose originally, seem to very strongly support the view that there is a double type of circulation in the spleen of higher animals and in the human spleen.

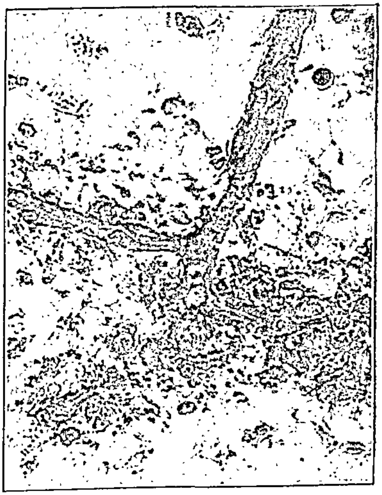
The solution of the problem of the circulation through the spleen is so necessary for the explanation of important forms of splenic disease that I wish to emphasise again some of the most salient points. It seems unlikely, in the first place, with the histological methods at present available, that we can hope

FIG. 4.



Mammalia (*Felis domestica*). Microphotograph of a cat's spleen washed out with saline solution before fixation. Shows two terminal arterioles (penicilli) with an ellipsoid on the end of each (low power). From a section kindly presented by Prof. J. P. Hill.

FIG. 5.



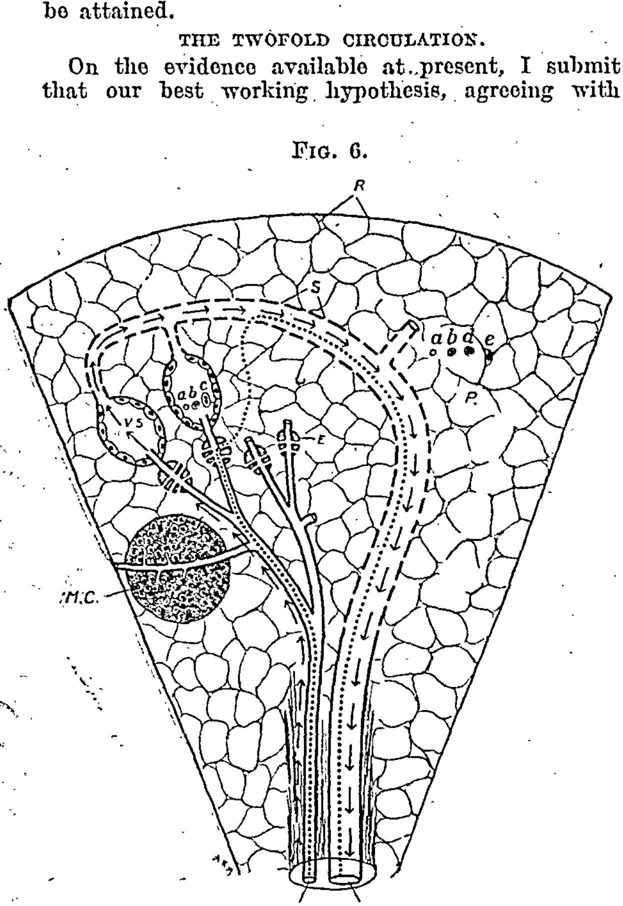
Part of an ellipsoid in a cat's spleen. Shows side channels which in this animal are lined by endothelial cells.

to solve the matter with certainty in the very complex spleens of man and the higher animals. In lower animals, histological methods have been of much service, but chiefly, I believe, because they have shown definite differences in the type of circulation in different animals—open in fishes, and closed in some reptiles. This, as I have stated, may serve to explain the great divergences of opinion regarding the splenic circulation expressed by different histologists during many years. It is only by experiments, and advances on those which have just been described, that a complete answer to our problem may finally be attained.

THE TWOFOLD CIRCULATION.

On the evidence available at present, I submit that our best working hypothesis, agreeing with many observed facts, is to regard the circulation through the human spleen as twofold. The first, or ordinary circulation going on continually, is a direct one, the blood being pumped through the splenic artery into venous sinuses, and from thence passing directly into the veins. The second circulation is intermittent, brought about by contraction and relaxation of the whole organ, and consists of an emptying of the pulp spaces through the wide stigmata into the veins and a filling again through the lateral channels in the walls of the ellipsoids. It seems probable enough, since minor alterations in the volume of the spleen are constantly taking place, that a small amount of blood is constantly being drawn out from the pulp into the veins to join the direct flow through the spleen; but the admixture of blood from the venous sinuses and from the pulp can, on this view, never be great unless the whole organ has undergone definite contraction.

FIG. 6.



Diagrammatic representation of a splenic lobule. The succession of arrows indicate closed splenic circulation, while the interrupted line shows open splenic circulation, through the pulp. *M.C.*, Malpighian corpuscle; *E*, ellipsoid; *V.S.*, venous sinus; *P*, splenic pulp; *R*, reticulum; *S*, stigmata in wall of vein. (*a*) Red blood corpuscle; (*b*) leucocyte; (*c*) endothelial cell from wall of blood-sinus; (*d*) lymphocyte; (*e*) multipolar cell of pulp.

The ellipsoids are certainly one of the most remarkable structures belonging to the whole vascular system, and there is nothing comparable to them in any other organ. Our knowledge of them has come almost entirely from the spleens of lower animals, since in the highly complex human spleen accurate study by histological methods is practically impossible. Tait and Cashin emphasised the important fact that the ellipsoids can act as potential valves, preventing any reflux of venous blood into the arterial system, and it is easy to realise how important this function may be when the spleen is contracting to empty the pulp. They are, in fact, the only valves or potential valves of the whole splenic vascular system, and it will be remembered that there are no valves in the main splenic vein or even in the portal vein. It is thus easy to see how, in conditions of increased portal venous pressure, the first obstruction, so far as the spleen is concerned, is at the ellipsoids. This is probably the deciding factor in reference to a characteristic lesion, the so-called "siderotic nodule," which is met with in a number of types of splenic disease.

It is well known since the experiments of Warthin, confirmed by Kellaway and myself (unpublished) that ligature of all the splenic veins, even when this is repeated at intervals in the same animal to occlude all newly formed anastomotic channels, does not lead to permanent splenic enlargement, but only to temporary acute swelling, followed ultimately by complete splenic atrophy. It is obvious that such experimental occlusion of the splenic veins is not strictly comparable with that caused by pathological thrombosis. Nevertheless, it is difficult to believe that complete obstruction of the splenic or portal veins, found in some cases of splenomegaly, can be the cause of the enlargement unless accompanied by independent pathological changes within the spleen itself. Experimental thrombosis of the splenic vein in one cat has been produced by a sclerosing solution of quinine and urethane (McMichael, 1931), but without resulting in splenomegaly.

Nerve-supply.

I shall have more to say about the general nervous control of the spleen in my next lecture. Here it is sufficient to state that the synapses of the autonomic nerves appear to be in the cœliac ganglion, and branches accompany the arterial supply to the spleen. Electrical stimulation of a nerve twig accompanying an arterial branch causes a striking segmental contraction, and the segments supplied by different branches do not overlap (Tait and Cashin). For the present the nervous control, except that which may be involved in the mechanism of generalised contraction of the organ, is of no known practical importance in disease.

Weight.

In concluding this lecture, a word or two may be said about the weight of the normal spleen, in animals and in man.

In vertebrates the spleen in comparison with the body-weight varies enormously, its relative weight being greatest in the fishes and least in the birds. In man many observations on the weight of the normal spleen at different ages were made by Henry Gray (1854), and he believed that the organ should be largest when most active in functional activity. In a series of 160 spleens he noted that the organ is largest during youth and active adult life (average weight 6–7 oz. in the adult), but that in old age the weight, both actual and relative to body-weight, decreases, until in those over 60 years of age the average is only 4½ oz.

The same question has recently been studied by *Gross* (1918–19), who has added many additional points of interest. He concludes that the spleen is heaviest and has its period of greatest functional activity early in life, and that by the age of 40 the functional activity of the organ has greatly declined. He maintains, moreover, that the histological changes which occur in the spleen with age have a most important bearing on the reactions of the organ to disease, and that middle life is the time when the organ shows its greatest reaction to irritants, using the word in the *broadest* sense.

REBUILDING OF CORBETT HOSPITAL.—It has been decided to rebuild Corbett Hospital, Stourbridge, in sections, and the first unit, on a site a short distance from the present buildings, is to be erected at once. The new block will have accommodation for 18 adults and 10 children and the cost will be £24,000, the greater part of which is already available.

NON-OPERATIVE TREATMENT OF THE SENILE PROSTATE.

BY J. CURTIS WEBB, M.B. CAMB.,
CONSULTING RADIOLOGIST, GLOUCESTER ROYAL INFIRMARY
AND
STUART LESLIE MUCKLOW, M.B.MANCH., D.M.R.E.,
HON. RADIOLOGIST, CHELTENHAM GENERAL AND EYE HOSPITAL.

THE changes in the prostate in the later years of life may be considered analogous to the climacteric changes in the female generative organs, and it appears somewhat of a slur on our profession that most medical practitioners have but one of two alternatives to offer to patients consulting them for the symptoms associated with senile prostate: either the horrors and risk of a catheter life, or the more serious procedure of surgical operation. The object of this communication is to draw attention to the treatment of the senile prostate by deep X ray therapy, or by diathermy plus static wave, or a combination of the two.

We fully recognise the wonderful results of prostatectomy in a large number of these patients, and we consider that, at the present day, it is indubitably the indicated treatment in a certain type of case. At the same time it is well recognised that operation often only gives partial relief, while in some instances complications or shock leave the sufferer even worse than he was before. The operation is far from being free of risk to life. The age of the patient is itself a source of danger. Sir John Thomson-Walker, in last year's Lettsomian lectures,[1] gives the mortality from 11 great general hospitals in different parts of the country from 1918–28 as 19·5, and in his own private practice as 6 per cent.

Ætiology of Prostatic Enlargement.

Kenneth Walker writes[2]: "All that can be said with certainty is that every cause that has yet been suggested is either definitely wrong or else insufficient alone to explain the facts."

There are two distinct types of simple senile prostate: the large elastic or soft, and the small hard. The problem requiring solution is whether these are completely separate conditions, or whether there is always a preliminary increase in the adenomatous elements with subsequent replacement of the glandular portion by fibrous tissue. The microscopic changes are very similar to those which occur in the female breast at the menopause—distension of the alveoli, tendency to develop intra-acinous growths as the result of epithelial proliferation, patchy distribution of these changes, and absence of round-celled infiltration. Whatever the origin may be, simple enlargement of the prostate resembles, in its gross and histological characters, an adenoma with a varying amount of cystic formation. It is therefore justifiable to assume that the soft hypertrophied prostate is definitely adenomatous and characterised by the new formation of epithelial cells. The absence of any round-celled infiltration would tend to disprove the contention of Chiechanowsky that inflammation is the primary cause of all senile prostates.

The explanation of the fibrous prostate, however, offers greater difficulties, and we venture to put forward the hypothesis that this form is the result of inflammation which may occur in two distinct ways. Firstly, an adenomatous condition may start in the prostate, resulting in a dilatation of the ducts of the peri-urethral glands whereby sepsis may invade the prostate from the urethra. A hyperplasia ensues, followed by the usual overgrowth of connective tissue and a final obliteration thereby of the glandular tissue, the end-result being that the gland becomes more or less a complete mass of fibrous tissue. On the other hand, excessive fibrous tissue may result from the irritation of chronic prostatitis brought about by causes such as excessive riding or bicycling, masturbation or sexual excess, or chronic gonorrhœa or other infection. Such a hypothesis as this is but a development of Ciechanowsky's theory, and puts aside the suggestion of Lannois that the condition is a degenerative fibrosis due to arterio-sclerosis—an explanation that is not accepted by such authorities as Thomson-Walker, Kenneth Walker, and Caspar, and Motz.

The symptoms are so well known that it is not necessary to enlarge on them, except to say that the early symptom of frequency is almost certainly due to nerve irritation associated with a hyperplasia of of the lining epithelium of the prostatic urethra and internal sphincter of the bladder, analogous with the symptoms of congestion of the mucous membrane over a deflected nasal septum. This explains why a large prostate may give rise to no symptoms and why, on the other hand, there may be definite urinary symptoms with little tumour formation (J. Lazarus [3]).

Principles of Non-operative Treatment.

The treatment of senile prostate by deep X rays, in combination with diathermy and static wave applications, is based on the following principles, which are well recognised.

(1) The selective action of rays of short wave-length in destroying newly formed cells and leucocytes.

(2) The effect of diathermy in promoting increased circulation in the part treated.

(3) The action of the Morton wave current in causing cellular contraction (histological massage) and thus aiding the increased circulation to get rid of the debris of the cells destroyed by the X rays.

It is remarkable that, whereas the medical literature of France, Germany, and America teems with articles from well-known workers approving radiotherapy for the senile prostate, hardly a reference can be found to it in the literature of our own country, except in two papers by Mr. T. E. Hammond [4] and Dr. Howard Humphris.[5]

It would be impossible to epitomise all the articles recently written on this subject, but a few are significant.

Boit [6] (1928) describes 58 cases (12 in the first stage, 13 in the second stage, 33 in the third stage), of whom 48 showed normal function of the bladder after X ray treatment. After two and a half years he traced 24 cases, all of whom remained cured. He considers radiation the method of choice for cases in the first stage, and both he and Hinze advocate it for old people.

Guilbert (Paris) reports 43 cases with 34 cures, one relapse, and five subsequent operations.

Joachim Fürstenau [7] describes his experiences at length. He discusses 59 cases (13 between 69 and 70; 27 between 70 and 80; 17 between 80 and 90; and two between 90 and 100), going in great detail into the condition of each, and states that 55 were cured or immensely relieved by irradiation.

Devois [8] writes of his favourable results and says that the treatment is especially indicated in cases where there are emphysema, chronic bronchitis, valvular or myocardial troubles, high arterial tension, diabetes, hæmophilia or old age, or where operation is refused by patient or relatives.

Guyon is equally enthusiastic, as are Thomas and Giles,[9] Pilger,[10] and Lazarus.

Ledoux-Lebard [11] (1924) critically examines the treatment and says that, though it is possible to get some relief by using the rays from ordinary X ray apparatus, immeasurably better results are obtained from a tube passing very hard rays (200 k.v.). With apparatus which will only pass currents not exceeding 130 k.v., the extra time of exposure required and the comparative thinness of the filter introduces an element of risk of damage to the intervening tissues and, owing to the rays not being sufficiently hard, an adequate dose does not reach the prostate. He issues the warning that at first symptoms may be increased from congestion, but that these can be overcome and then relief is obtained. He urges the wisdom of repeating the treatment at intervals.

In addition to the above we have found over 20 articles on the subject in foreign literature, couched in the same favourable language.

REASONS FOR NEGLECT OF RADIOTHERAPY.

We cannot but feel that the unfavourable light in which many genito-urinary specialists in this country view the treatment is due first to faulty technique, secondly to insufficient care in selecting suitable cases, and thirdly to a misconception as to certain effects which may follow the treatment but which, though *post*, are not necessarily *propter hoc*.

(*a*) Some surgeons have stated that X ray therapy makes a subsequent prostatectomy more difficult owing to fibrosis. Kenneth Walker, though writing unfavourably of the treatment (after an experience with X rays in five cases only), states: "It does not interfere with enucleation should this become necessary." This view is borne out by all foreign authorities, and Sir James Berry informs us that he has not found that radiotherapy increases the difficulty of subsequent operation for exophthalmic goitre. He further agrees with us that, when an operation was difficult owing to fibrosis, the fibrosis was a factor of the disease and not the result of antecedent X rays.

(*b*) Retention has occurred immediately after treatment. This is due to a temporary congestion that frequently takes place after adequate X ray dosage and, though catheterisation may be necessary for a few days, benefit is usually noticed as soon as the congestion subsides.

(*c*) Rectal ulceration, or other X ray damage, is just as much a fault of overdosage as in any other part of the body and, except in an extraordinarily radio-sensitive patient, ought not to occur.

(*d*) The possibility of damaging the skin at the site where an incision would be made in a subsequent prostatectomy is fully discussed under the heading of technique, and can easily be avoided.

(*e*) A much more difficult question to decide is whether or not to remove all senile prostates, considering that it is stated that 16 per cent. of glands removed for simple enlargement have been found to show malignant changes. Now the mortality from prostatectomy is so high that the risk of operation would seem to balance the danger of malignancy. On the other hand, we have in X ray therapy a form of treatment without risk and one which will be beneficial even if cancerous cells are already present. We cannot but feel, therefore, that in cases where examination does not give rise to any suspicion of the presence of malignancy and where other factors indicate that radiotherapy can be employed with reasonable anticipation of success, it is right to recommend such treatment. The possibility of latent early malignancy is another strong argument for the use of the most deeply penetrating rays.

Indications and Technique.

The treatment is indicated for all early cases, and for later cases when there is no large amount of residual urine (i.e., exceeding 2–3 oz.) and no definite enlargement of the gland into the bladder, as shown by cystoscopy. These signs, as well as evidence of back pressure on the kidney and the presence of cystitis, are contra-indications. Joachim Fürstenau, of Königsberg, employs radiation even where there is cystitis, after washing out the bladder for a time and administering urotropin.

Where benefit results from treatment it is important that the patient should have a further series if the symptoms return (which they not infrequently do, as the condition is progressive). It is quite possible to keep them in abeyance almost indefinitely by this treatment.

The present method is to work at 200 k.v. (kilovolts) and to attack the gland through the perineum, two inguinal fields and two fields on either side of the coccyx, making five fields in all. Four-fifths only of the unit skin dose is given to the perineum, the skin in this region being usually moist and rather liable to damage by the rays; the full dose is given to the other four fields. Recognising the risk of damaging the skin for subsequent operation we protect a central strip of the abdomen, 3 in. wide, from the symphysis to the umbilicus, and only direct the ray through the inguinal regions. For access to the perineum we seat the patient on a special stool, similar to an office stool in form and height, a chair placed in front of it serving as a foot-rest. This special stool has an aperture about 10″ × 6″ cut in the seat and the X ray tube is placed beneath the seat, the compressor pointing upwards through the opening. The top of the stool, excepting for the aperture, is completely covered with lead rubber, while a piece of the same material hangs down in front to protect the patient's legs. The advantages of this method are obvious: the buttocks are held widely separated, permitting ready access to the perineum; the patient is comfortably seated instead of lying in the lithotomy position; and there is no possibility of sparking from the ends of the tube into the patient. A filter of ½ mm. zinc—4 mm. aluminium and a focal surface distance of 30 cm. are used.

In treating the lateral fields we use a modification of the method devised by Chaoul which entails the use of two special pieces of apparatus.

The first consists of a wooden box, 15″ × 15″ × 12″, the lid of which carries a fluorescent screen, action side facing inwards. The side of the box is open and a mirror is fitted in it at an angle of 45°, so that the image of the fluorescent screen can be easily seen through the open side. The second requirement is a lead ball about ¼ in. diameter which is soldered on to a piece of stiff copper wire about 6 in. long. The room is darkened and the following procedure is carried out, using the minimum amount of artificial light. With the patient lying on his side the lead ball is inserted into the rectum to such a distance that it comes in contact with the prostate. The patient then turns on his back and the tube is centred over Poupart's ligament, being inclined so as to direct the rays slightly inwards. The Chaoul box is then placed under the couch directly beneath the prostate area, and a small current is passed through the tube. All lights are now extinguished, and the operator, lying on his side, looks into the Chaoul box, where he can see the map of the fluorescent screen illuminated by the rays. Wearing a lead rubber glove to protect his hand, he moves the carrier until the shadow of the lead ball appears in the centre of the field, when the central ray will be passing through the prostate gland. This aim is greatly facilitated by the use of a flat diaphragm of thick lead with a central opening 1 in. in diameter, which is slipped inside the compressor ordinarily used for treatment. A small circular field of illumination is thereby obtained, making the localisation more exact, and the shadow of the lead ball more clearly visible. This adjustment having been effected (and it should only take a minute or so), the compressor is brought down on to the patient, using as much pressure as can be tolerated. The lead diaphragm and ball are then removed and the treatment given. Care must be taken not to forget to remove the lead ball, as it would form a centre of strong secondary radiation which might easily lead to ulceration of the rectum. This method is employed in the treatment of both inguinal and coccygeal fields. In both cases a filter of ¼ mm. zinc—3 mm. aluminium is used. The front is treated at 30 cm. focal surface distance, and the back at either 23 cm. or 30 cm. focal surface distance, according to the thickness of the patient.

The supplementary diathermy and static applications begin as soon as the radiotherapy is completed and are given daily or on alternate days over a period of three weeks. For the diathermy we use a rectal electrode similar to that devised by Cumberbatch, while the other electrode is placed just above the symphysis and over the area of skin which was protected during the radiotherapy, the skin which has been subjected to the rays being thereby avoided. For the static wave applications it is necessary to use a machine capable of generating a satisfactory charge at slow rotation, and it is important to treat with slow impulses using the maximum length of spark obtainable.

In cases where the prostate is small and hard it is often sufficient to use only the combination of diathermy and static wave, as radiotherapy has but little effect on the purely fibrous prostate.

The general results that we have obtained in the treatment of simple senile prostate have been so encouraging that we have summarised the 16 cases that we have had the opportunity of treating. While it may be said that the number is small—and it is indeed so in comparison with those of some of our Continental colleagues—we bring them forward in the hope that some serious attention may thereby be drawn to this form of treatment, and also that some of our own colleagues may be persuaded to enter the lists and give their experiences of the treatment of the condition by X rays and other electrical methods.

Cases.

Case 1.—Age 72. Very large elastic prostate with early symptoms of retention and residual urine about 5 oz. Frequency two-hourly day and night. State of heart contra-indicated operation. Both frequency and retention much improved for five months subsequent to treatment; then, following a motor accident, the patient's nerves were much shaken and the symptoms were aggravated. A further course of X ray, diathermy, and static wave were given and he improved for eight months; then, the retention getting worse, he was operated on with complete success. The surgeon said that there was no evidence to suggest that the radiotherapy had caused *fibrosis. Although a successful* result was in this case doubtful from the start, owing to the retention and large quantity of residual urine with almost certainly a large middle lobe, the patient wished to try anything rather than be operated on—a view in which the surgeon concurred.

Case 2.—Age 77. Large medium-hard prostate. Frequency two-hourly at night, four to five times during the day. Was catheterised every week. After treatment much improved. Frequency twice at night. A year later he reported that improvement was maintained unless he did horse-riding. He has now left the neighbourhood and we cannot trace him, but 18 months ago—i.e., four years after treatment—we learned that he was going on well and that his general health was excellent.

Case 3.—Age 65. Large elastic prostate, no evidence of retention. Residual urine about 2 oz. Day and night frequency. He was treated in 1924. This year he writes: "I have never ceased to be thankful that I underwent the treatment instead of operation. I generally go through the night without being disturbed." His general health is much improved.

Case 4.—Age 78. Large hard prostate. Evidence of commencing retention and some residual urine. Frequency five times at night and two-hourly by day. Had monthly catheterisation. Two years after treatment his doctor reported that on the rare occasion when he passed a catheter it went in quite easily, whereas previously there had been great difficulty, and that the frequency was now only twice a night and the patient could hold water for three and a half to four hours by day. Shortly after this report he died of heart trouble.

Case 5.—Age 60½. Increased frequency by day and night with difficulty in starting. Prostate large, smooth, and elastic. In 1928 (four years after treatment) patient came to report that he had been much better but that he thought symptoms were returning. Treatment was repeated and benefit has lasted till now.

CASE 6.—Age 67. Frequency three to four times at night, two-hourly by day. Some pain. Prostate not much enlarged; smooth, flat, rather hard. Treated in 1927. Reports in 1930 that the day and night frequency is much less and the improvement is maintained, and adds, "I have derived very great benefit from the treatment."

CASE 7.—Age 69. Prostate rather hard, not enlarged. Frequency three times at night and about six times during day. Occasional slight hæmorrhages. Treatment in 1925. He now reports that he has been much better since and that, although on some days he passes more water than on others, there is no discomfort or inconvenience. He hunts regularly.

CASE 8.—Age 67. Had several attacks of hæmaturia. Prostate enlarged and soft. Neither X ray nor cystoscopic examination revealed the cause of the bleeding. No *B. coli.* Slight frequency, though not very marked. Treated 1928. From then up to last June there was no bleeding, and the patient writes: "There was no doubt as regards frequency that this trouble was lessened after the treatment." Since June he has been again cystoscoped, and there are fears that the cause is malignant disease of the bladder.

CASE 9.—Age 78. Prostate very large, smooth, elastic. Frequency three or four times at night, very often in the day. Residual urine 2½ oz. Treated 1928. After a year he reported: "Can sleep all night without being disturbed. Much less frequent by day. Feeling very well." This improvement is still maintained.

CASE 10.—Age 72. Prostate large and soft. Residual urine 2 oz. Day and night frequency marked. Treated April, 1928. Immediately after the treatment the frequency increased. Various means were tried, but in June he got acute retention; cystotomy and subsequent prostatectomy were necessary. It is very difficult to trace the relation between the treatment and subsequent events, for the retention in June could not have been due to prostatic congestion from the radiation, as the interval of time was too long. It was the breaking-down of the wound after operation in this case that made us abandon the suprapubic route in raying the gland.

CASE 11.—Age 72. Prostate enlarged, elastic. Some day and night frequency. Treated May, 1929. We heard that he was relieved and in much better health after the treatment.

CASE 12.—Age 61. Prostate rather small and hard. Frequency about three times at night. Treated May, 1929. Reports that he now gets up twice instead of three times at night, but otherwise not improved.

CASE 13.—Age 79. Prostate rather small, hard, smooth, not tender. Frequency four to five times at night. Every two hours by day. Pain and difficulty in starting. Treated June, 1929. In October, 1929, reported "infinitely better in every way." Now there is no pain or discomfort and flow starts much more easily. Frequency is less, and general health is excellent.

CASE 14.—Age 78. Prostate enlarged. Frequency three times at night and very often during the day. Heart and lung condition contra-indicated an operation. Treated February, 1929, but died in October from pyelonephritis and uræmia. His son, a medical man, wrote: "He certainly had been more comfortable since the treatment and only had to be catheterised at long intervals."

CASE 15.—Age 78. Prostate large, hard, smooth. Difficulty for some years. Frequency seven to ten times at night and one and a half to two hours by day. No X ray evidence of stone. Treated by diathermy and static wave only in April, 1930. After 12 treatments flow started easily. Frequency was only once or twice at night, and he could go three hours during the day. This month he reported that there is no relapse and he can shoot two or three days a week.

CASE 16.—Age 79. Pain and difficulty on micturition for 12 months. Frequency six to seven times at night and two-hourly by day. Treated by diathermy and static alone in June, 1930. Writes this month: "I am considerably better, nights much freer from trouble, and I am feeling more like I was a year ago before the prostatic trouble began. If I should relapse I shall call on you once more for your help."

Summary.

1. Surgical interference is called for in all cases of senile prostate where there is much residual urine, definite enlargement into the bladder as proved by cystoscopic examination, cystitis, or evidence of back pressure affecting the kidney.

2. Where the above conditions are not present, deep radiotherapy with or without diathermy and static wave is to be employed. In cases of small hard fibrous prostate the last two forms of treatment alone often give the best results. The non-surgical methods are also indicated: (*a*) in early cases; (*b*) where the heart, lung or general condition, or age of the patient, contra-indicates operation; (*c*) where the patient or his friends are unwilling for surgical interference unless absolutely necessary.

Where relief has been obtained it is important that the patient be kept under regular periodic observation; for the condition is a progressive one, the symptoms may recur, and further application may be necessary to keep the progress of the malady in check.

No mention has been made of ultra-violet therapy or prostatic massage, since the treatment described above is regarded by us as infinitely superior.

CAVERNOUS SINUS THROMBOSIS:

A FATAL COMPLICATION OF MINOR FACIAL SEPSIS.

BY W. G. SCOTT BROWN, M.B. CAMB.,
F.R.C.S. ENG. & EDIN.,
MEDICAL OFFICER, SEVENOAKS HOSPITAL.

THE present series of six cases of cavernous sinus thrombosis is collected from the records of St. Bartholomew's Hospital for the period 1922 to 1930. Three of the cases are described at some length, though only one case came under my direct care. This condition was first described from post-mortem findings by Abercrombie (1818) and Duncan (1821). The first clinical record was made by Vigla (1839). The differential diagnosis was discussed by Knapp in 1868, while Dwight and Germain (1902) were the first to attempt surgical treatment. Up to the present about 350 cases have been recorded, and in a series of 140 cases collected by Dorland Smith (1918) 35 per cent. were due to infection of the face or orbit with a spread to the cavernous sinus through the ophthalmic veins. A further 40 per cent. were secondary to ear infections, 13 per cent. to infections of the mouth and throat, 9 per cent. to the nose, and 32 per cent. to other causes. Only cases falling into the first group are discussed in this paper.

Anatomy.

The anatomy and the connexions of the cavernous sinus are a matter of the first importance in understanding the pathology, symptomatology, and treatment of this condition. Roughly quadrilateral in shape, tapering from behind forward and about 2 cm. in length, the cavernous sinus is situated on each side of the body of the sphenoid and extends from the sphenoidal fissure in front to the apex of the petrous portion of the temporal bone behind. Above and to the outer side is the temporosphenoidal lobe, while the optic tract, the crus, and the pons are superior relations. In the adult the cavernous sinus is only separated from the sphenoidal air sinus by a thin plate of bone. The sinus is trabeculated and contains the carotid artery and the sixth nerve, which lie on its internal aspect against the wall of the sphenoidal air sinus. The third, fourth, and fifth nerves run forward to the sphenoidal fissure in the external wall.

The cavernous sinus on each side receives blood from the middle cerebral veins, the sphenoparietal sinus, the veins from the sphenoidal air sinus, and from the superior and inferior ophthalmic veins. A communicating vein joins the superior ophthalmic to the angular vein, which is often of considerable size. The angular vein is formed by the junction of the supra-orbital and frontal veins and is continued down the side of the nose as the anterior facial vein, which is joined by many small tributaries from the subcutaneous venous plexus on the side of the nose. Other connexions of the cavernous sinus are mainly efferent channels, though this by no means precludes these channels as routes of spread of thrombosis. The superior and inferior petrosal sinuses pass from the cavernous to the lateral sinus, and emissary veins pass through the base of the skull to join the pterygoid venous plexus, which provides an indirect communication between the cavernous sinus and the soft palate, fauces, and pharynx, and the alveolar processes of the upper and lower jaws. The circular sinus connects the cavernous sinus to that of the opposite side.

In the cases under consideration the connexions which carried the infection are those from the face, and particularly from the nose and upper lip, by way of the subcutaneous plexus and the angular and ophthalmic veins. Logan Turner (1926) demonstrated by a series of sections through the nose, orbit, and the base of the skull that the spread from the nose to the cavernous sinus took place by this route; this was confirmed in the present series by a dissection of the veins in Case 1, sections being taken at intervals to confirm the thrombosis, which could be seen macroscopically.

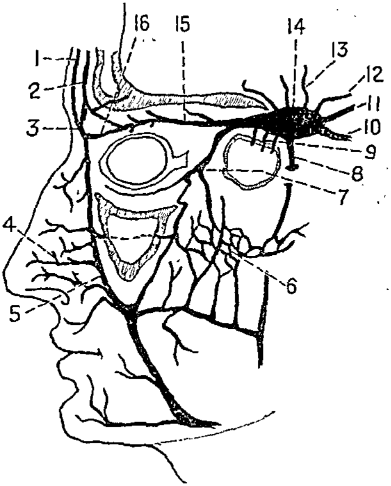
Pathology.

The process of thrombosis in a vein or a venous sinus depends upon three factors: degenerative change in the vessel wall, sluggishness of the blood stream, and pathological changes in the blood. These factors are intimately related, though in various conditions one may stand out above the rest. Thus slowing of the blood stream and impaired vitality of the vessel endothelium are of chief importance in the formation of a simple thrombus, whereas in the infective variety it is the organisms or toxins in the blood which are the determining factors in the thrombosis.

The spread of infection from the septic focus to the sinus may take place in three ways. Firstly, a clot may form in a vein near to the focus; infection follows, giving rise to a further spread of thrombosis. Secondly, there may be a diffusion of toxins along the perivascular lymphatics, with a transmural spread to the endothelium of a vein or sinus. Lastly, a particle of a thrombus which has reached a tributary may be dislodged and carried to the sinus as an embolus. However the clot forms, it eventually becomes infected and pus is formed which, if carried into the general blood stream, gives rise to pyæmic abscesses in the various organs of the body.

From the material collected in this series of cases it is impossible to say by which method the infection spread, but from the dissection of the veins of the nose and orbit in one case (Case 1) it was obvious that the process was one of direct spread by the lumen of the vein or by the lymphatics, as in all the areas involved the veins contained blood-clot or pus which was continuous from the *angular* vein to the cavernous sinus. Further, *in Case 2*, the vessels in the meninges showed the spread of infection taking place by the perivascular lymphatics. Sections made from the less damaged *inferior* ophthalmic veins showed a marked perivascular infiltration by *polymorphonuclear* cells and organisms. The latter could be seen *in the* endothelium of the veins, and a few in the lumen. In Cases 1 and 2 a similar condition could be made out in the cerebral veins which were in close relation to the cavernous sinus. This suggests that the method of spread in venous thrombosis is lymphatic diffusion of the toxins, but the fact could only be demonstrated by obtaining from a case a series of sections which would show a point reached where there would be either perivascular inflammation but no endothelial change, or endothelial damage and thrombosis which had outstripped the perivascular spread.

FIG. 1.



Venous connexions of the cavernous sinus. (1) Frontal vein; (2) supra-orbital vein; (3) angular vein; (4) nasal vein; (5) anterior facial vein; (6) pterygoid venous plexus; (7) inferior ophthalmic vein; (8) vein of Vesalius (inconstant); (9) veins from sphenoidal air sinus; (10) inferior petrosal sinus; (11) superior petrosal sinus; (12) sphenoparietal sinus; (13) middle cerebral sinus; (14) cavernous sinus; (15) superior ophthalmic veins; (16) communicating vein.

Any of the areas drained by the cavernous sinus may be the site of infection giving rise to a septic thrombosis. Infection may spread from the middle ear by way of the lateral sinus, from the sphenoidal and ethmoidal air cells, from the mouth, tonsils and teeth, from osteomyelitis of the diploë and, as in the cases at present under consideration, from minor sepsis on the face.

In the six collected cases, the primary focus was a nasal furuncle in two, an infected insect bite on the nose in one, an infected cut on the nose from a stone chip in one, and a carbuncle on the upper lip in two cases. In three cases the nature of the infection was investigated and found to be staphylococcal, as would be expected. In each of the six cases the body reacted to the local bacterial irritation by the usual processes of inflammation. The failure on the part of the protective mechanism to shut off the infection completely may have been due to several factors. Poor resistance on the part of the patient would favour a spread of infection, but was not present in all the cases. The virulence of the organism is an important factor. The absence of valves in the angular and ophthalmic veins and the large size of the angular vein makes the route easy for spread to take place. It is noticeable that the cases of severe open lacerations of the face and nose, in which there is a mixed infection of staphylococci, streptococci and other virulent organisms, are not complicated by cavernous thrombosis; it is the furuncle or its counterpart—usually small and often staphylococcal—which appears to favour this serious complication. The difference in the conditions seems to lie in the diffusion of toxins at considerable pressure from the abscess cavity, when such pressure has not been relieved by adequate drainage. The fact that the results of incision appear to favour the spread of thrombosis is discussed below.

Once thrombosis of the blood in the sinus has taken place, the spread of the infection with pus formation rapidly follows, and the recovery of the organisms from the circulating blood or even from the urine is an indication of the pyæmia resulting from a failure to shut off the infection in the vein. This is confirmed at post mortem by evidence of pyæmia as shown by pyæmic abscesses, which are eventually present in many organs in all cases which survive long enough. The presence of organisms in the cerebro-spinal fluid indicates the direct spread to the meninges.

Signs and Symptoms.

The first symptoms suggesting a serious complication of a small infective focus on the face are malaise and headache. Case 1 was a child who had been stung on the nose by an insect, and the doctor was consulted because of the headache. An incision was made, but she still complained of severe headache which became steadily worse. Case 2, a railwayman, who had been injured on the nose by a splinter of stone, complained two days later of a " septic place " and headache. He came to hospital next day because he was alarmed about the frontal headache, which had become more severe. He died 48 hours later. The headache is usually frontal, but may radiate to the occiput or be situated over the mastoid process.

Pyrexia is a constant feature. In three of the cases a temperature of 100–101° was noted by the doctor, and in all cases 101–106° was recorded in hospital. The pulse-rate is often not very much raised to begin with, but later usually rises to 120. The white blood count is raised, and increases as the invasion progresses. If the white count falls the prognosis becomes very grave, as this indicates a failing resistance.

Vomiting and rigors are by no means constant, and in only one case was vomiting an early symptom. Rigors occurred in one case at an early stage, but both symptoms were present in the advanced stages in association with a general pyæmia. Drowsiness was present in two cases as an early symptom, but was accompanied by restlessness or delirium at night.

The most important local signs are found in the eye. Orbital cellulitis is one of the first to be seen, but does not give definite evidence of intracranial disease, as it may be due to a spreading cellulitis in the soft tissues around the septic focus. Marked conjunctival œdema is more suggestive, whereas proptosis and chemosis are definite indications of a retro-orbital thrombosis. Corneal ulceration and any internal or external ophthalmoplegia are due to interference with the fifth or with the third, fourth, and sixth nerves in relation to the sinus and, if found accompanying the other symptoms make a diagnosis of cavernous sinus thrombosis certain. It is interesting to note that the earliest paresis is often of the external rectus, due to the position of the sixth nerve within the sinus. Papillœdema may be found, though it is often impossible to see the retina because of the difficulty of looking through a misty cornea. The patient usually dies before papillœdema develops, but an examination should always be made, as venous congestion, thrombosis, or hæmorrhages may be seen. The pupil is at first small but later is fixed and dilated. Vision often fails early, owing to the pressure on the eyeball or stretching of the optic nerve.

Later signs and symptoms are in the main those of the complications. Accompanying a spread of infection to the lateral sinus is an increased probability of rigors, with pain behind the ears and tenderness along the line of the deep cervical glands. Signs of inflammation seated deeply in the neck may be due to a spread of thrombosis to the internal jugular vein, to perivascular inflammation, or even suppuration in the carotid sheath (see Case 1). Meningitis is almost invariably present as a terminal event and was found in the four cases on which a post-mortem examination was performed. Pyæmia was observed in two cases though it was only recognised clinically in one case.

The cerebro-spinal fluid is found to be under pressure and opalescent, with a diminished sugar content. It contains many polymorphonuclear leucocytes and cultures yield staphylococci.

Differential Diagnosis.

The diagnosis of cavernous sinus thrombosis does not usually present any difficulty when once the condition is established. In the early stage the severe headache, and later the proptosis and chemosis, are a guide. The following conditions may present difficulty in diagnosis.

Orbital cellulitis occurs as a complication of infections of the nose and upper lip and may be followed by thrombosis of the sinus. The signs of swelling of the lids, redness, conjunctival œdema, and conjunctivitis are common to both conditions, but proptosis does not occur until the sinus is involved.

Meningitis rapidly complicates sinus thrombosis and may largely overshadow its signs, but the condition of the orbit and eyes differs from any primary meningitis.

Sphenoidal sinusitis may simulate sinus thrombosis very closely, and in one case seen recently there was headache, a raised temperature and pulse, and œdema of both eyelids, and on the second day proptosis of the right eye. The condition cleared up completely after exploration and drainage of the sphenoidal and ethmoidal cells. It is obviously of the greatest importance to decide between these two conditions, and the sinusitis can only be diagnosed by careful examination of the nose assisted by transillumination, radiography, and if any doubt still exists by exploration of the sinuses.

Pulsating exophthalmos is said to be caused by thrombosis of the cavernous sinus. It must be a very rare sign, and if it does occur the other causes need not be considered, as they are all chronic or non-infective conditions.

Treatment and Prognosis.

Septic thrombosis of the cavernous sinus is invariably fatal unless the actual sinus is drained. Bircher (1893) reported one case which he drained successfully by boring through the petrous portion of the temporal bone. The importance of early diagnosis and focal treatment becomes obvious, owing to the lack of success of radical treatment, in spite of many attempts by many different routes. Once the sinus contains an infected thrombus, however, drainage gives the only hope of recovery. There are several possible routes of approach.

First, there is the Hartley-Krause Gasserian ganglion route, of which the most obvious disadvantages seem to be the risk of meningitis if it does not already exist and the fact that the sinus has to be incised in the wall that contains the important structures. Attack through the orbit is possible but only at the sacrifice of structures in the sphenoidal fissure, so that this method would be of use chiefly in cases in which the orbit was the primary focus. Approach through the petrous bone, though giving the only reported success and showing that recovery may be effected by bold treatment, is an extremely severe operation and leaves the patient deaf and with a facial paralysis. A nasal approach, through the wall of the sphenoidal air sinus, described independently by Luc in France and Grunert in Germany, offers the greatest likelihood of success. The sphenoidal air sinus can be drained comparatively easily, and through the superolateral wall the cavernous sinus can be reached without great risk of injury to important structures such as the carotid artery or sixth nerve and to a lesser extent the third, fourth, or fifth nerves, and again the risk of meningitis as a result of operation is diminished. By operations on the cadaver it has been shown by these observers that an approach through the canine fossa and maxillary antrum of one side into the sphenoidal sinus of the opposite side gave a line which, after penetrating the lateral sphenoidal wall, entered the cavernous sinus, and this procedure was followed in a number of cases without injury to any important structure.

General treatment with specific antisera or vaccines may be tried, or bactericides may be injected into the blood stream. In the present series one case was treated with 10 c.cm. of mercury perchloride, 0·1 per cent., intravenously, though with no appreciable good effect.

Preventive measures, by efficient observation and treatment of all conditions liable to give rise to cavernous sinus thrombosis, are by far the most important lines of treatment. Ear infections usually come to an otologist before the cavernous sinus symptoms develop. The ethmoidal and sphenoidal air sinuses must always be remembered as a possible source of infection, and in this instance again it is usually in a special department that the condition will be finally diagnosed. It is in the cases of minor facial sepsis that the opportunity of making an early diagnosis of this severe complication may fall to the lot of any medical man. The furuncle or insect bite or other small septic focus is not serious enough to be sent away for hospital treatment; if it is already in the casualty department, the house surgeon will be in charge of the case.

In any case of minor facial sepsis, especially when the "danger area" is involved, headache should be regarded with suspicion, and if the headache is becoming worse in spite of local treatment of the focus, thrombosis of the sinus should be suspected. Giddiness or a feeling of drowsiness or dullness, and an unduly high temperature and pulse, will single out in a few months at a general hospital perhaps 20 cases of the type that may develop cavernous sinus thrombosis. Malaise is an indefinite symptom, and some authorities state that the onset is usually associated with euphoria.

Free incision and squeezing are generally recognised as dangerous and some authorities advise conservative means only. Hinton (1927) advises hot flax seed poultices and Speer (1929) advocates hot dressings of a saturated solution of magnesium sulphate. Mainzer (1930) states that "surgery of the face in minor infections is bad surgery" and recommends hot applications only.

While recognising the risk of opening up uninfected tissue and lymph spaces, and dislodging thrombi and breaking through the barrier of leucocytes, it seems obvious on general surgical principles that the pus should be evacuated at the earliest time it can be done with safety.

The following suggestions are given in detail as being safe and efficient methods of dealing with the focus, drainage being obtained without the involvement of healthy tissue.

For small septic foci about the nose and eye, puncture should be made with a sharpened match-stick dipped in liquid carbolic acid. For larger abscesses, hot applications should be employed until the first sign of pointing can be seen. The skin over this area is then removed and, if any pus escapes, a small pledget of cotton-wool soaked in 10 per cent. cocaine should be lightly packed into the cavity. A few minutes later an orange-stick dipped into *liquor hydrargyri nitratis acidus* should be gently bored into the core. Care must be taken that all bleeding has stopped and that the wound is dry before the acid is applied, as otherwise the skin may be burnt by an overflow of acid. The treatment is painful, as the acid soon burns past the cocainised area. This method rapidly improves the local condition without the danger of free incision, and may be repeated if necessary.

In the case of a neglected carbuncle of the face, particularly of the upper lip, if there be any of the warning symptoms of sinus thrombosis, the carbuncle should be excised and carbolised, and not incised with undercutting of the flaps as is often practised in order to obtain a good cosmetic result. A plastic operation can restore the lip, whereas inefficient excision and drainage may lose a life.

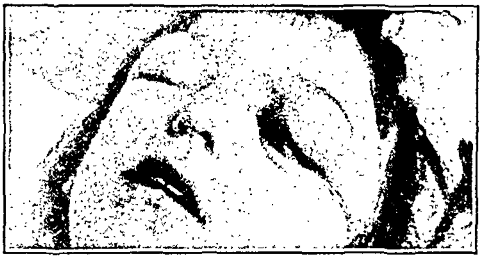
Six Case Reports.

CASE 1, a girl, aged 10, was admitted on Sept. 8th, 1924, complaining of "headache and swelling of both eyes." Eleven months before she had had an "abscess" in the nose following many colds. Seven months before she had had measles, and a discharge from the ear which had ceased five months earlier. Eight days previously there had been a small abscess on the nose on the site of an insect bite; five days before admission she had had sleeplessness and had been feverish; on the next day the doctor had been called in and her temperature had been 100·4° and her pulse-rate 88. She had had severe spasmodic frontal headache. There had been no sweats, rigors, or vomiting, but she had been very restless. Her eyes had appeared natural and her reflexes normal. Peripheral reflexes had been present and equal on both sides. Three days before admission the abscess had been incised and the pus evacuated. One day before, at 6 A.M., swelling of the left eye had commenced and had been marked by midday. On the morning of admission there had been extensive swelling in the left orbital and temporal region. There had been muco-pus in the left conjunctival sac and some œdema of the right lids. The temperature had been 101° and the pulse-rate had been 98. In the evening the temperature had been 103°. There had been no vomiting, rigors, or sweating.

On admission she looked ill, and lay still, moaning. She cried when handled, but would answer questions and tell her age. She complained of frontal headache. Her eyelids were bluish-red and œdematous. Her eyes were tender, more on the left than on the right. Conjunctivitis was present, but no nystagmus or ophthalmoplegia. There was doubtful proptosis of the left eye. There was tender fullness on both sides of the neck behind the angle of the jaw, decreasing downwards, greater on the left than on the right. No definite swelling was felt. The tongue was furred. A small furuncle was situated on the tip of the nose to the right side, and was discharging freely. The nasal mucosa was inflamed, but no pus or muco-pus was seen. The abdomen and limbs showed nothing abnormal. Reflexes were present and equal.

Examination of the eyes showed the right cornea clear but a vitreous haze; a slight degree of papillœdema was present. The left disc was not seen owing to corneal mistiness. The left maxillary antrum was opaque to transillumination but the frontal sinuses appeared normal. Nothing abnormal was discovered in the urine.

FIG. 2.



Photograph taken on Sept. 9th. The infected insect bite can be seen on the right side of the tip of the nose and is surrounded by an area where the skin is dry and scaly. The left eye is proptosed, the conjunctiva is projecting through the palpebral fissure, it is plum-coloured and there is a sero-sanguineous discharge trickling from the eye. The right eye is proptosed to a lesser degree than left though seen more clearly in the photograph. The œdematous condition of the forehead may be made out immediately above the bridge of the nose and is continuous with swelling of the forehead.

On the next day the swelling increased, extending up into the scalp for two inches. On the left it was limited by the attachment of the temporal fascia, and on the right it had spread from the orbital region to the area in front of and below the ear. There was extreme tenderness over this area but not over the mastoid process. There was no redness of the skin and the superficial veins were not engorged. Œdema of the eyelids was very marked. There was proptosis of both eyes, more marked on the left than on the right. Chemosis was present, the conjunctiva being extruded through the palpebral fissure on the left side. Swelling extended down the neck and obliterated all the fossæ on the left side of the face. There was extreme tenderness.

X ray examination showed the left antrum opaque. The ethmoidal cells were hazy on both sides, more markedly so on the left. The frontal, mastoid, and sphenoidal air cells appeared clear. The temperature was 103° and the pulse-rate was 128. At 4 P.M. rigidity of the neck was present. Reflexes were absent in the upper and lower limbs and in the abdomen. The Babinski response was extensor on both sides and Kernig's sign was positive. Lumbar puncture yielded 20 c.cm. of opalescent cerebro-spinal fluid under pressure; its withdrawal was followed by improvement in the pulse and more regular breathing. The cerebro-spinal fluid clotted in 15 minutes. There was an increase of albumin and a slight increase in the globulin; Fehling's solution was not reduced. The blood count revealed 7800 white cells and over 1500 polymorphonuclear leucocytes per c.mm. Staphylococci were found in films and cultures.

On the next day there was left hemiplegia. There was marked chemosis in both eyes and a serosanguineous discharge. Proptosis had increased. The left inferior nasal fossa contained blood-stained pus. On Sept. 11th the temperature was 104° and the pulse-rate 140. The patient died at 5.45 P.M.

Post-mortem Examination.—A diagnosis of furuncle of the nasal skin, cavernous sinus thrombosis, meningitis and pyæmia was made. The right orbit was removed intact, including the cavernous sinus posteriorly, and the angular vein and skin of the nose anteriorly. It was hardened in formalin and a dissection made at a later date. The superior ophthalmic vein was dissected from the angular vein to the cavernous sinus as it lay deep to the superior rectus and the levator palpebræ superioris. It was filled with greenish-yellow pus and was bathed in pus in places, the wall of the vessel having broken down. The inferior ophthalmic vein showed areas of thrombosis, though it mostly contained pus.

There was meningitis at the base of the brain and over the right motor area. The veins on the surface of the dura were thrombosed and the middle meningeal vein on the left side contained pus. Both cavernous sinuses and the circular sinus contained pus. The lateral sinus and jugular bulb were not thrombosed. The left carotid sheath was bathed in thick green pus, which had apparently spread from the pharyngeal plexus of veins. The superficial veins of the forehead, when cut across, were seen to be filled with pus. The heart, lungs and kidneys showed small abscesses.

Microscopic examination showed that there was acute basal meningitis. The pia-arachnoid was much thickened and congested. There was dense polymorphonuclear infiltration. Fibrinous exudate was present in the meninges but with little hæmorrhage. There was no inflammation of the brain substance. Staphylococci were seen in the inflamed meninges. The mucous membrane lining the sphenoidal air sinus showed œdema of its submucous cellular tissue but no evidence of active inflammatory change when stained by hæmatoxylin and eosin. No organisms were seen when stained with Gram's stain.

The coats of the carotid artery in the petrous bone were normal. The lumen was filled with clot, part of which may have been ante-mortem, as seen by the denser peripheral clot. The periarterial lymphatics were seen to be loaded with polymorphonuclear cells when stained by hæmatoxylin and eosin. Gram-positive cocci in groups were seen in the peri-arterial lymphatics and tissues; also a few colonies in the lumen of the vessel, indicating that the dense part of the clot was probably an ante-mortem mural clot.

CASE 2, a railwayman, aged 23, was admitted on July 28th, 1924, complaining of "headache and swelling of the left eye." Two days before, while he was sifting some small stones, a fragment had flown up into the left nostril. He had removed it ten minutes later. On the next day there had been a slight swelling on the left side of the bridge of the nose, and headache in the left orbital region. He was admitted in the evening with swelling of the left side of the nose extending into both eyelids.

On admission the patient looked ill; his temperature was 100·4° and his pulse-rate 72. There was swelling of the lids, conjunctival œdema, and chemosis. The left eye was proptosed and fixed; the tension was increased but the fundus was normal. There was a red tender swelling to the left side of the bridge of the nose, involving the left eyelids and extending across to the right. No abrasion was seen in the vestibule and nothing abnormal could be seen in the anterior nares. There was no tumour or tenderness along the line of the jugular vein, and no enlarged lymph glands were palpable. There was rigidity and tenderness of the posterior muscles of the neck. The reflexes were normal.

An incision from the inner part of the supra-orbital margin, extending downwards beside the nose, was made and the lacrymal bone and frontal process of the superior maxilla were exposed and the anterior ethmoidal cells opened. No pus was found. The middle and posterior ethmoidal cells and then the left sphenoidal cell were opened. The mucous membranes were œdematous but no pus was found. All the tissues were very congested and bled freely. The left middle turbinate was removed and free connexion between the ethmoid cells and nasal cavity made. A drainage-tube was inserted from the anterior nares to the sphenoidal sinus.

The cerebro-spinal fluid was turbid with spontaneous clot. Fehling's solution was not reduced. The blood count showed many polymorphonuclear cells. No organisms were seen in film and no growth obtained on culture. Sensitised streptococcal vaccine (one hundred million) was given. On July 30th the patient became comatose. The temperature was 106°, the pulse-rate 158, and the respiration-rate 31. The patient died at 5 P.M.

Post-mortem Examination.—The diagnosis was abscess of the left ala nasi, bilateral cavernous sinus thrombosis, and basal meningitis.

In the operation area there was an unhealed scar on the left side of the nose which continued back into the ethmoidal region. There was no apparent connection between the operation area and the cranial contents. The left ala nasi was the site of deep-seated pus. The superior ophthalmic veins were thrombosed. There was bilateral thrombosis of the cavernous sinus and circular sinuses, which contained pus. Basal meningitis was present in the region of the cavernous sinuses. The pus contained staphylococci.

Microscopic examination showed acute meningitis; the pia-arachnoid was much thickened, congested, and infiltrated with polymorphonuclear cells. There were areas of hæmorrhage into the meninges. Similar cellular infiltrations were seen around the vessels, spreading along the perivascular sheaths, and in the walls of the veins but not of the arteries. Gram-positive organisms (staphylococci) were present in large numbers in the meninges.

CASE 3, a woman, aged 48, was admitted on March 21st, 1923, complaining of "inability to see clearly out of the left eye." Five days before she had noticed a small red, painful spot at the corner of the mouth on the left side. Next day the swelling and pain had increased and had spread to the left eyelids; there had been epiphora. On the next day the mouth had been painful and there had been shooting pains in the left eye. Two days before admission the pain had become worse, with headache and soreness of the tongue. The day before there had been discharge of yellow material from the corner of the mouth. The patient had vomited on three occasions.

She walked into hospital and, though her vision was noticeably impaired, the mental condition was quite good. Headache was not a prominent symptom. The temperature was 103° and the pulse-rate 110. At 2 P.M. headache was present and becoming severe. On the left side the eyelids were very much swollen, red and shiny. Conjunctival œdema, a slight degree of chemosis, proptosis, and corneal ulceration were present. There was a slight swelling of the lids of the right eye and conjunctival œdema. The pupils were equal in size and reacted normally. The swelling of the left eye was continuous with a swelling on the left of the nose and the main swelling at the left angle of the mouth. This was hot, red, and discharging yellow pus, with a slough visible externally and in the mouth. It was not very painful.

An operation was performed at 5 P.M. and an incision of the septic focus was made at the angle of the mouth; the cavity was scraped and packed. At 12 midnight the patient was roused with difficulty, and was later unconscious. The temperature was 107·4° and the pulse-rate 160. No evidence of meningitis was obtained. She died next day at 2.30 A.M.

Post-mortem Examination.—The diagnosis was carbuncle on the upper lip, bilateral cavernous sinus thrombosis, basal meningitis, and pyæmia.

Conjunctival œdema and hæmorrhages were found in the orbit, worse on the left than on the right. Thrombosis was present in the cavernous sinus and circular sinus, with some suppuration, and the meninges showed acute inflammation over the pons. Infarcts at the base of the right lung were beginning to suppurate. There was early pleurisy over these areas.

Microscopic examination revealed fatty degeneration in the heart muscle cells (osmic stain); one small area of polymorphonuclear-celled infiltration of myocardium was present. A section of the posterior part of the lung through an infarct was made; there was hæmorrhage and polymorphonuclear infiltration, with abscess formation. Acute suppurative meningitis was present round the pons.

CASE 4, a woman, aged 30, was admitted on Nov. 13th, 1923, complaining of "severe headache and swelling of the eye." Fourteen days previously there had been a small abscess on the left side of the nose, which was very painful and swollen, and some headache. The abscess had been treated with fomentations and had discharged and healed, but the headache had persisted. Four days before admission the headache had become worse and there had been throbbing in the back of the neck, in spite of treatment, with a temperature of 100·5°. The day before admission the temperature had been 101·8° and the pulse-rate 85. There was much œdema, proptosis and photophobia of the right eye, and œdema and photophobia of the left eye. Knee-jerks had increased.

On admission at 9 A.M. the patient looked ill; her temperature was 104·5° and her pulse-rate 120. She had a dusky, cyanosed appearance. The eyelids were closed with the œdema, conjunctival œdema was marked, bilateral proptosis was present but no lesion on the nose was visible. The patient died at 4 P.M.

At the *post-mortem examination* proptosis was still marked. The cavernous sinuses and pituitary fossa contained pus which welled up from the cavernous sinus. The pontine area showed early acute meningitis and some meningeal hæmorrhage. The accessory air sinuses were normal.

CASE 5, a woman of 26, was admitted on March 3rd, 1921, complaining of "swelling of the face and pains all over the body." Six days previously there had been a small septic spot at the angle of the mouth on the left side. Four days before she had been "feverish" and had had pains all over, and three days before she had been treated with "serum." She was sent to hospital as acute parotitis.

On admission the patient looked ill; the temperature was 103·4°, the pulse-rate was 118, and the respiration-rate 44. Nothing abnormal was noticed in the eyes except a swelling of the left lids. A very painful, red swelling was present on the left side of the face, extending to the right side. In the chest there was pleural friction at the right base.

At operation a carbuncle was excised, which was found under anæsthesia to be situated deeply in the cheek, with sinuses inside the mouth.

On March 4th the temperature was 104°, the pulse-rate 110, and the respiration-rate 28. Increased swelling of the face, orbital cellulitis and conjunctival œdema were noted. On March 5th the temperature was 104°, the pulse-rate 110, and the respiration-rate 48; proptosis was present. On March 6th at 12.30 A.M. the temperature was 106·4°, the pulse-rate 150, and the respiration-rate 48. The patient died.

CASE 6, a man, aged 20, was admitted on Jan. 28th, 1926, complaining of "severe headache." A week previously there had been a furuncle on the left ala nasi. Four days before there had been swelling on the left side of the nose and the left eye, the temperature had been 101° and the pulse-rate 88. There had been no chemosis or proptosis. Two days before admission the temperature had been 98·2° and the pulse-rate 68. The swelling had diminished and the eye had been normal. The patient had vomited and complained of headache. The day before admission he had again vomited and the headache had still been present. Stiffness of the left side of the face and some œdema of the left lids had been present, but the eyes had been normal. He had been given 10 c.cm. of antistreptococcal serum. There had been severe headache at 10 P.M.

On admission the temperature was 100° and the pulse-rate 90. The patient was very ill and semi-conscious. There was swelling, œdema, redness and pain about the left orbit. Proptosis of the left eye was present and its movements were impaired and the reaction sluggish. There were no signs of meningitis. An incision in the left orbital region for cellulitis was made. There was hæmorrhage and some purulent material from small localised abscesses. The temperature was 104° and the pulse-rate 140. The patient died at seven in the morning on the next day.

Conclusions.

1. Cavernous sinus thrombosis occurs in a small percentage of cases of infection about the nares and upper lip. 2. It occurs owing to the close and free connexion between the angular vein and the cavernous sinus. 3. It occurs as a result of small infective foci in which the tension is high, resulting in a rapid diffusion of the toxins with the invasion of a vein from without. 4. Headache, which increases in spite of treatment to the focus, suggests this serious complication. Chemosis and proptosis are signs which leave no doubt that thrombosis has occurred. 5. Orbital cellulitis is usually associated with the cause of cavernous sinus thrombosis and should be considered in the diagnosis. Sphenoidal and ethmoidal sinusitis may be confused with this condition. 6. A method of treating the septic focus which avoids the dangers of free incision is suggested. 7. The treatment of the infected sinus is palliative, though drainage by one of the routes described may be attempted.

I am indebted to Mr. W. D. Harmer, Mr. F. A. Rose, Mr. L. B. Rawling, Prof. G. E. Gask, and Mr. Harold Wilson for permission to publish these cases.

SPONTANEOUS TUMOURS IN MICE.

INFLUENCE OF DIET AND AGE.

By Sir Leonard Hill, M.B. Lond., LL.D., F.R.S.,
HON. ADVISER FOR RESEARCH, LONDON LIGHT AND ELECTRICAL CLINIC.

Cancer is rarely seen in a population living a simple and natural life, says F. L. Hoffman, after investigating the incidence among the natives of America from the Arctic to the Falkland Islands. McCarrison and Halliday had each reached this conclusion through prolonged experience of the hill tribes of India. Similar reports have been made of Northern Nigeria and Abyssinia by Dyce Shrap, of the Orange Free State by Fouche, and of West Africa by Tippier. Cancer was formerly never seen among the Basutos by Casalis de Pury, but now, since the introduction of infections such as syphilis, and of alcohol, by civilised people, cancer has become common, and also among the negroes of the United States of America. In British Guiana the negroes are reported to have twice as much cancer as the Indians; the latter are mainly agriculturists, and of simpler habits of life.

The cancer cases reported by Kuhne as seen among Chinese in a hospital in Canton Province were one-tenth as numerous as those seen in the Edinburgh Hospital. In Greenland only nine cases among Esquimaux were recorded in five years (Hindhede). The nomadic races of the Near East no less show a relative immunity to cancer which is ascribed by Fallscheer Zürcher to their simplicity of life. The French Canadians, who are farmers, are reported to have only half the incidence of cancer of the British Canadians (Guest). Havana City shows, says Hoffman, a high cancer mortality-rate, while in the rest of Cuba the rate is relatively low.

Cancer is particularly a disease of old age, and it has been said that natives die too young to develop cancer; also that death certification is so bad that one does not know what they do die of. Against this argument is to be set the fact that the clergy in Britain, who are longest lived, are least subject to cancer. Coalminers, butchers, and publicans, who live less long, have two or three times the cancer-rate of the clergy (occupational mortality figures for 1910–12).

CANCER AND DIET.

It is claimed in popular health papers that a deficiency in the diet of civilised people, of essential substances, such as vitamins, is a cause of cancer. Against this view may be put the fact that the cities of Denmark show the highest cancer mortality in Europe, while the use of sugar and sweets therein is not excessive.

Again, Russians in the cities, who did not eat white bread, had a cancer mortality about equal to that in England. In Holland there is more cancer of the food canal and less of the breast and uterus than in England, while in Italy the cancer mortality-rate is altogether lower.

The Jews, who show a tendency to obesity and diabetes, like the Dutch, have more cancer of the food canal and less of the reproductive organs. In Germany the statistics show the digestive organs among males to be the chief seat of cancer, and next the skin, while among females the reproductive organs head the list, and next the digestive organs and then the skin. An investigation of the vital statistics of a number of houses of Catholic religious orders showed that cancer occurs in a population abstaining from flesh food, and lent no support to the view that among such populations the relative incidence of cancer is low (Greenwood and Copeman).

Hoffman thinks that the irritation of the food canal by eating too much may be a predisposing factor in cancer causation. Young fowls undergoing intensive feeding are said to show a noteworthy percentage of tumours.

Fujimaki observed epithelial proliferation and small papillomata in the gullet, fore-stomach, bladder, &c., of rats fed on a diet deficient in vitamin A. In one case there was found a tumour of the lung, taken to be a metastasis, but the illustration of this shows that it was really one of the spontaneous tumours so commonly found in the lungs of rats and mice. Cramer found such proliferations no less in some old mice fed on ordinary laboratory diets, and Erdmann and others were unable to produce tumours of the stomach by a diet deficient in vitamin A.

McCarrison has contrasted the effects on rats of an ill-chosen diet with a well-selected one. The bad diet led to intestinal and pulmonary disease, and villiform papillomatous outgrowths occurred in the fore-stomach, but no cancer resulted. During several years of experiment both he and Cramer have never found evidence of cancer being caused in animals by ill-chosen diets. Underfeeding may delay the growth of spontaneous tumours, but is disadvantageous to the life of mice in the case of very malignant tumours (Rous).

It has been claimed by Maisin and others that a diet of liver and whole meal enhances the production of tar-cancer, when compared with a diet poor in vitamins, but this appears to be due to the animals living longer on the liver diet. Cramer was unable to confirm this claim.

After a review of the evidence the Imperial Cancer Research Laboratory reported that "there is no reliable evidence, experimental, statistical, or clinical, which would indicate a causal correlation between cancer and the absence, or the presence, or the excess of any particular dietetic constituent. Sensational statements to the contrary are unfounded and ill-considered, and only serve to alarm the public."

ACTION OF IRRITANTS.

Long-continued sources of irritation are known to be causes of occupational cancer—e.g., tar, soot, hot charcoal in the kangri pots used in Kashmir, X rays, mineral oils—all these may produce cancer of the skin, while aniline, naphthylamine, and benzidine may produce cancer of the bladder. Chronic ulcers of the stomach, duodenum, and neck of the uterus not uncommonly result in cancer. Irritation due to chronic constipation is said to be a cause of cancer of the colon. For the induction of carcinoma, says Cheatle, "the irritant must be applied directly to the actual cells, which are eventually the parents of the tumour, and there is a time factor which appears to depend upon the intensity of the application." Thus Fibiger by feeding rats on the larvæ of a nematode (*Spiroptera neoplastica*), isolated from the muscles of cockroaches, induced gastric cancer in over 50 per cent. of these rats. The freed larva burrows superficially in the stomach lining and there develops to maturity, inducing the epithelium to proliferate and become cancerous. The nematode may lodge in the tongue, but not in the gullet or any other part of the alimentary canal.

By injecting tar into the stomach of a rat a squamous-celled epithelioma has been produced in the cardiac portion of that organ of the same type as that produced by infection with this nematode (*Menetrier*). Cancer has been produced in the rectum in one out of 16 mice, and in the mouth in one out of 10 mice, by the injection on alternate days of 0·1 c.cm. of 50 per cent. alcohol into one or other orifice (Krebs). It is claimed by Bagg that mammary cancer can be produced in mice by ligating the ducts of the gland.

There is evidence that humoral conditions affect the development of cancer. Thus it is said that tumour tissue, excised and autolysed under suitable conditions, when inoculated makes animals hypersensitive to the growth of transplanted tumour (Chambers and Scott). Cramer excised and minced up the spleen and returned it to the peritoneal cavity in a number of mice. Cancer resulted from tar-painting of the skin much earlier in these than in other mice.

EVIDENCE OF INCREASE OF CANCER.

While statistics drawn from the records of autopsies made in Glasgow Infirmary showed no spectacular increase in cancer in recent years, an increase in cancer of the colon was more evident than of any other site. In the United States of America cancer mortality is reported to be increasing mostly in regard to the food canal, and the foreign-born have a much higher rate than the native-born in this respect; possible factors which appear common to the foreign-born in the United States of America, and to the lowest social class in Britain are a poor diet and bad teeth, alcohol, and syphilis. Sources of chronic irritation have time to act with age, and thus an investigation of almost 1000 autopsies at a French hospital for the aged showed incidence of cancer in 7·7 per cent. (Roussy).

The Bureau of Census, Washington, 1929, showed the relation of age to incidence of cancer per 100,000 as follows:—

Years.	1925.	1926.	Years.	1925.	1926.
Under 5	3·2	3·6	35–44	59·4	59·8
5– 9	1·5	2·2	45–54	165·9	163·0
10–14	1·7	2·1	55–64	382·5	361·2
15–19	3·3	3·6	67–74	743·2	708·9
20–24	5·0	5·3	75 and over	1070·8	983·6
25–34	15·5	15·8			

Three-quarters of the apparent increase in the cancer mortality of Scotland is attributed to the increasing proportion of older people in the population, and the rest mainly to improved methods of diagnosis.

The expectation of life at birth has been extended by some 17 years, and mostly by saving the children. The mortality-rate between the ages of 20 and 50 has, however, fallen, and when the crude death-rates from cancer are standardised for the change of population at each age group an apparent increase of 25 per cent. drops to one of only 4 per cent., and most of this increase is due, according to Shearer, to better diagnosis and more accurate certification of the cause of death in the aged.

HEREDITY AND CANCER.

The inheritance of a tendency to cancer has been much discussed. In one family a sarcoma occurred in several generations, and in the same situation (Manson), while Warthin, in four families, found evidence of inherited susceptibility to cancer, and Griffith Evans has recorded two families with apparent strong hereditary susceptibility. Werner thinks that the nature of the environment is the potent cause; consanguineous marriages, frequent in certain families, do not, he says, increase any such susceptibility. Most conclusive is the fact that the actuaries of insurance companies find no evidence of inheritance of cancer. In Switzerland the average death-rate for 1911–13 per 10,000 inhabitants aged 40 or over has been, for departments containing a majority of the race *Homo europæus*, 30·63, for departments containing a majority of the Cevenal race, 14·57, and for departments containing a majority of the race *Homo meridionalis*, 13·90 (Pittard).

Strains of mice have, however, been bred which show greatly increased susceptibility to spontaneous cancer, and these strains must have either inherited this susceptibility or been subject to transmission of some cause of infection which results in cancer. Maud Slye has published pedigree charts illustrating inheritance of cancer, but the evidence on which these are based is not very convincing. Lynch has secured 65 per cent. of mammary gland tumours in the first strain of females bred from mice with a high incidence of this tumour. Marsh has bred a strain of mice in which no less than 90 per cent. of the breeding females were subject to mammary carcinoma; the males did not develop this cancer. Dobrovolskara-Nzavadskaia crossed a female mouse affected with mammary cancer with a non-cancerous male and secured a stock of which almost 50 per cent. were affected with cancer. But, says Cramer, in the case of all such stocks, on continued inter-breeding, the high cancer-rate does not appear to continue. Lynch claims that susceptibility to tumour formation produced by tar-painting of the skin may be inherited. Crossing a less susceptible stock with a highly susceptible one, and tar-painting the progeny, increased the incidence of lung tumours greatly.

Borrel believes in infection—e.g., with a nematode—as the cause of spontaneous mouse cancer; a control experiment appears to be required in which females of a low susceptible stock are kept with females of a highly susceptible stock. The experiments given below show a varying, but often high, incidence of tumours, which may be due to infection, although the cause has not been detected.

Experimental Observations.

To study the influence, if any, of age, diet, and bedding materials on the occurrence of spontaneous tumour, a stock of mice were selected at random from the common breeding stock, which had been kept for some years under good conditions at the National Institute for Medical Research. The stock so taken was maintained, bred from, and kept going by Miss M. Brad for six years under the best conditions of cleanliness and care. Mates were chosen at random for breeding, and the males and females not so used were kept apart, for males, if brought up together and not mixed with females, do not fight. The mice in each successive stock were kept till they naturally died, excepting those with obvious tumours. These were killed when the tumour became large. Autopsies were done on all mice, and microscopical preparations made of any tumours. At first Dr. J. M. Murray, and later Dr. J. R. Perdrau, kindly confirmed the nature of the tumours which were found.

Three years in a mouse corresponds to very old age in a man; the process of growing to maturity and of decadence with advancing age can be studied in this period of time.

Stocks of mice were kept on different diets and on different bedding. Some were kept on what approximates to a natural diet for wild mice: (1) barley, oat, and wheat grain, and fresh green food; some on (2) canteen lunch diet, cooked meat, and vegetables with the usual amount of common salt added, and pudding and tinned fruit; some on a (3) canteen tea diet, one poor in vitamins, white bread and margarine, rock cakes and biscuits, and a little milk; some on (4) a diet found by Dr. A. B. Hill to be the average one of Essex farm labourers, low in protein value; and some on (5) the same diet, a third part of which had been browned by frying, in order to see whether cancer-producing products were produced in food by such burning. Some of the stocks were fasted two days each week, so as to observe the effect, if any, of such abstinence.

The following beddings were tried on mice fed on Diet 1: (1) sawdust and elastin (fine wood shavings); (2) sawdust and cotton-wool; (3) peat and hay; (4) peat and cotton-wool; (5) peat and elastin; (6) sawdust and hay; (7) hay and cotton-wool. The mice on the other diets were kept on cotton-wool and sawdust.

Cancers have occurred indifferently in mice on all diets and on all beddings. The significant influence has been age. In mice dying under 1 year, 2 per cent. of the tumours occurred; in those dying between 1 and 1½ years, 8 per cent.; in those dying between 1½ and 2 years, 40 per cent.; in those dying between 2 and 2½ years, 34 per cent.; and in those dying between 2½ and 3 years, 16 per cent. These figures are striking as the number of mice diminished with age and few lived over 2½ years. The mice fed on the tea diet were healthy, but small in size, could not breed, and in old age were liable to skin troubles, which could be set aside by addition of green food. Tea diet with hay as a bedding produced mice larger in size and able to breed; the seeds in the hay added necessary vitamins. Diet 5, one-third fried, proved less favourable than the diets 1, 2, and 4, on all of which mice grew to be fine healthy animals and bred well. Elastin as a bedding is not so warm as cotton-wool, and mice on this bedding are, in consequence, more active and do not grow so large.

Only one stock, and that a small one, died out just before reaching the age of one year; the loss of this stock was due to pneumonia, a common cause of death among tame mice. The animals were kept in a room at about 60–65° F., and no definite relation was noted between season and weather conditions and deaths from pneumonia. The research began with a stock of 44 males and 44 females, and 35 stocks in all were bred, giving a total of 793 mice, of which 400 were males and 393 females. There spontaneously occurred among these mice 140 tumours of the lung, 76 mammary carcinomas, 29 tumours of the liver, 23 lymphomata, 3 tumours of the thyroid, a few tumours of the ovary, testis, bowel, and some epitheliomata, totalling in all 303. Tumours occurred in 31 per cent. of the males and in 49 per cent. of the females. The higher percentage in females was due to mammary carcinoma. Tumours occurred in those fed on a poor vitamin diet and in those fed on a rich one. They occurred in those on the diet of raw grain and green food even more than in those on a cooked diet. They occurred also in a stock kept on an artificial diet of casein, rice starch, salt mixture, cod-liver oil, and marmite. In the case of the over-cooked diet the number of tumours was large in two stocks, but small in a third, and nil in a fourth one, but these two stocks died out soon after one year was reached. One stock of mice on Diet 1 were fasted throughout life for two days a week, and even for three days a week for one month; the mice made up weight on the non-fasting days, but remained smaller although as sleek, healthy, and long-lived as well-fed stocks. Tumours occurred in this stock during old age no less than among other stocks. The conclusion then was reached that diet had no definitely significant influence on the occurrence of tumours, nor had the character of the bedding any influence, as shown by the Table (Diet 1). The incidence of tumours varies in stocks on the same diet and bedding as shown in Table I. just as much as it varies between stocks on different diets.

TABLE I.—*Diet 1: Raw Grain and Green Food.*

Bedding.	No. of mice.	Males.	Females.	Total tumours.	In males.	In females.	Mammary.	Lung.	Liver.	Lymphoma.

Diet 1 and Fasting on Two Days a Week.									
11	5	6	7	4	3	—	4	1	1

Tumours in 63 per cent. of the mice.

While the incidence of tumours has been very high no obvious source of irritation has been found. Tapeworm cysts in the liver were occasionally found, but no connexion of these with tumour formation was evident. No nematodes were observed. Tumours of the lung were the most frequent; such tumours claimed to be metastases, or induced by tar, may then, in some cases, be spontaneous.

CONCLUSIONS.

Spontaneous tumours occurred frequently in a stock of mice kept in excellent hygienic condition. The incidence varied considerably in successive stocks which were raised over a period of six years by random in-breeding. The variations in Table I. on the same diet and bedding are large. Different diets, or beddings, had no apparent significant influence on the incidence. Tumours of the lung were common, and may, perhaps, be associated with the liability of mice to pulmonary infection.

Tumours of the Lung.

Tumours of the lung were observed by Harland in 103 out of 275 mice having spontaneous tumours; a very high percentage of all spontaneous tumours observed in mice by Tysser were in the lungs. Many of these tumours are circumscribed, but may grow to a size which destroys life; others are infiltrating and malignant in character. It is recognised that so-called benign tumours—e.g., tar-warts—may become malignant, and it is not just then to exclude the tumours of the lung from the list of spontaneous cancers.

When the lungs of old mice are examined microscopically, localised foci of inflammation are often to be found. With this liability to microbic infection may go chronic irritation, and the tendency to formation of tumours. Patches of inflammation are not infrequently to be found in the lungs of mice when killed in apparent good health. Overgrowth of epithelium and papillomata of minute size are often to be found in those lungs in which tumours are microscopically evident. Similarly, in the lungs of four human cases of squamous-celled carcinoma of the bronchi, observed by Feyrter, there were found at a number of places, and in bronchioles far removed from the tumour, overgrowths of epithelium and papillary growths of the mucous membrane. In one of these cases an early carcinoma was only detected microscopically.

Feyrter associated the increase of bronchial cancer, which he says occurred after the great influenza epidemic (1918–19), with the inflammatory changes produced by this disease.

In a stock of mice observed by T. Cherry, in which the incidence of spontaneous tumours was 6 per cent., inoculation of small numbers of tubercle bacilli beneath the cuticle raised the incidence to 55 per cent. in males and 71 per cent. in females. Tumours occurred not only in familiar sites in the mice, but in the thyroid, pylorus, colon, pancreas, prostate, and bladder. The tubercle bacilli were taken to be the essential agent in promoting this tumour formation. Lumière claims that carcinoma is a disease of cicatrices; a trauma starts proliferation of cells and some humoral modification comes into play to produce a cancer.

There is a disease of South African sheep called *jagsiekte*, in which proliferation of the alveolar epithelium results as part of an inflammatory process. Cell masses, sometimes papillomatous, grow out from the alveolar wall and fill the cavity. Invasion of the interalveolar tissue also occurs. Some of the epithelial proliferations can be traced to the lining of the bronchioles.

Through irritation by dust cubical alveolar cells become detached and act as phagocytes, such cells may possibly be excited to form a tumour by long-continued chronic irritation.

Schabad tarred the skin of 107 mice for six to eight months and two to three times a week. There survived 96 over three months and 79 over six months. There occurred in 22 a tumour or tumours of the lung, and all these showed either cancer or precancerous lesions of the skin. In those surviving over six months there were lung tumours in 27·8 per cent.

Through frequently painting the skin of mice with tar lung tumours resulted in 66 per cent. of a stock of mice, observed by Murphy and Sturm. R. E. Smith, on the other hand, found tumours of the lungs only in 4 per cent. of mice which were submitted to fumes of tar or to exhaust gases, or painted with gasoline, a figure no greater than that in other stocks of mice which were kept in normal conditions.

Increase of cancer of the lung in man has become evident in mortality returns—e.g., in the United States of America, from 0·6 (1914) to 1·9 (1929) per 100,000, and has been ascribed to the breathing of dust from tarred roads. This increase may be due in part to longer life and better diagnosis—e.g., by X rays. Carcinoma of the lung formed, however, 5·4 per cent. of all carcinomata in Germany 1920–21, and no less than one-seventh of malignant tumours seen during the last five years in the post-mortem room of St. Bartholomew's Hospital were intrathoracic in origin (Maxwell and Nicholson). In the Schneeberg mines in Saxony cancer of the lung has been for years the most significant cause of death, and arsenic in the mine dust has been suggested as a factor.

This research was carried out in the National Institute for Medical Research.

PAY BEDS FOR MIDDLE-CLASS CHILDREN.—The Cheyne Hospital for Children, at Chelsea, has provided a small private ward for children suffering from affections which require prolonged treatment, which is said to be the only one in a London hospital of this type. The weekly charge varies from £3 3s. to £5 5s., and the fee payable to the physician or surgeon is subject to confirmation by the hospital authorities. The ward has a southern aspect and overlooks the Thames and the Chelsea Embankment.

UNUSUAL COMPLICATIONS OF DIPHTHERIA.

By E. Noble Chamberlain, M.D., M.Sc. Liverp., M.R.C.P. Lond.,

SENIOR HON. ASSISTANT PHYSICIAN, ROYAL SOUTHERN HOSPITAL, LIVERPOOL;

AND

Stanley Alstead, M.B. Liverp.,

ASSISTANT MEDICAL OFFICER, CITY HOSPITAL FOR INFECTIOUS DISEASES, LITTLE BROMWICH, BIRMINGHAM.

PERMANENT HEART-BLOCK.

Complete heart-block during diphtheria does not seem to be an uncommon complication when the myocardium is severely affected. A detailed description of the clinical findings in diphtheritic heart-block has been given by Korach [1] who described two fatal cases. In recent years numerous references to the subject have appeared and many electrocardiographic records have been published. Thus Stecher [2] has reported 19 cases of complete auriculoventricular dissociation. Two cases with notes on the post-mortem findings have been described by Marvin and Buckley.[3] Allen [4] has also published a case but without electrocardiographic tracings. All these cases appear to have terminated fatally, and this result is in agreement with the experience of Harding.[5]

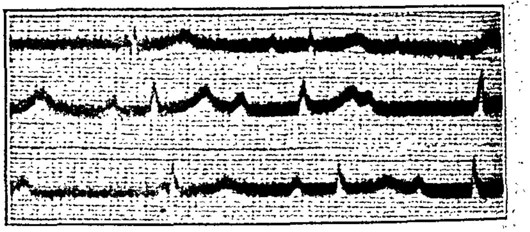
Transitory heart-block, partial or complete, has been noted by many observers, but few of the cases in which heart-block has been complete have recovered, death having occurred from circulatory failure or some other cause such as diaphragmatic paralysis. Ducamp and Janbon,[6] however, have described a single case characterised by complete heart-block in which recovery did take place and the normal rhythm was re-established.

Only very occasionally, it seems, does evidence of a damaged myocardium persist after diphtheria. Parkinson [7] has published the "first undoubted case" of heart-block in diphtheria which later gave place to auricular fibrillation, the latter condition being present on re-examination of the patient after six months. In an interesting article by Reid,[8] details of a case of permanent bradycardia are given and reference is made to a case of complete heart-block following diphtheria, described by Read.[9] Butler and Levine [10] have recently emphasised the importance of diphtheria as an ætiological factor in the production of late heart-block. The comparative rarity of heart-block as a permanent condition following diphtheria justifies the publication of the following case:—

Case 1.—A woman, aged 28, had been admitted 18 years previously to the Birkenhead Infectious Diseases Hospital suffering from diphtheria. She had had no previous illnesses. The diagnosis of diphtheria was confirmed by repeated bacteriological examinations. Peripheral neuritis affecting the hands and feet occurred as a complication in the course of the disease. The patient states that antitoxic serum was given but no details of the treatment are now available. She was discharged from hospital after six weeks. Recovery from the effects of peripheral neuritis was complete in about nine months, but during the first few weeks of convalescence the patient had several "heart attacks" characterised by præcordial pain and dyspnœa. These symptoms disappeared and have not recurred. Her present condition is very satisfactory; she looks well and states that she enjoys perfect health. On moderate exertion however, she is conscious of her heart "bumping" though no irregularity is noticed, and she becomes "crimson in the face." There is no history of fainting attacks or fits. For many years the patient has ridden a bicycle nearly every day without any ill-effects.

The apex-beat of the heart is in the fifth intercostal space, three and a half inches to the left of the midline. The rhythm is quite regular and the rate about 40 beats per minute. The cardiac thrust is easily palpable but there are no thrills. The mitral and aortic second sounds are apparently slightly accentuated, otherwise all the heart sounds are normal. There is a soft systolic bruit at the mitral area conducted about two inches towards the left axilla and there is a short aortic systolic murmur which is not conducted. There are no signs of cardiac failure. The arteries are barely palpable at the wrist and the blood pressure is 124/64. The urine is normal, the tonsils quite healthy, and the Wassermann reaction negative. Electrocardiograms (see Figure) show complete heart-block.

The interest of this case lies principally in the permanent defect of conductivity following diphtheria. Most diphtheritic affections of the heart are essentially of an acute nature, disappearing within a year of the illness, but the present case is an example of a small but definite group of cases in which the heart is permanently damaged by diphtheria. It is also instructive to note that in spite of a permanent and complete heart-block existent for many years no Stokes-Adams seizures have occurred and no subjective or objective signs of heart failure.



Electrocardiogram, showing complete heart-block.

DIPHTHERITIC HEMIPLEGIA.

The subject of diphtheritic hemiplegia has recently been reviewed by J. D. Rolleston,[11] who points out that since the condition was first described by Sir William Gull in 1859 barely a hundred cases have been recorded. Cases which have come to autopsy show that the lesion is vascular in origin and due to embolism, thrombosis, or hæmorrhagic encephalitis. It appears that embolism is the commonest cause and is attributed to an apical endocarditis (Marfan [11]). Diphtheritic endocarditis affecting the mitral valve and causing mitral incompetence is unusual, especially when associated, as in the case mentioned below, with hemiplegia which developed during the acute stage of the condition.

Case 2.—The patient, a girl aged 18, had diphtheria when 7 years of age. The only illnesses she had had previously were chicken-pox and whooping-cough, otherwise she had been healthy in every way. The disease affected the fauces and the diagnosis of diphtheria was confirmed by bacteriological examination. Hemiplegia developed while the patient was very ill during the third week of the illness. At first it was a flaccid paralysis affecting the face, arm, and leg on the right side, but later spasticity developed in both limbs. The doctor who attended the case recalls that the heart was severely affected during the illness and the prognosis was considered to be very poor. Seven weeks after the onset of diphtheria the patient was admitted to an isolation hospital suffering from scarlet fever, and at the beginning of this illness it was noted that the child's heart was already damaged. Recovery from scarlet fever was rapid and uneventful.

Until 12 months ago she had no cardiac symptoms. Lately, however, she has complained of shortness of breath on exertion associated with præcordial pain, stabbing in nature, lasting for a few minutes and completely relieved by rest. The paralytic condition has persisted since the onset, and though there has been a gradual improvement there are signs of early contracture.

The right arm and leg are spastic and wasted and have exaggerated tendon reflexes. The plantar reflex is extensor in type on the right side and flexor on the left side. There are brisk abdominal reflexes on the left side but those on the right are diminished and sluggish. There is a slight right-sided facial paresis. The pupils are equal and react normally. On the left side there is a slight internal strabismus. The organic reflexes are normal, though there has been dysuria for the past four years which appears to be functional in type and not connected with the illness. There are no sensory changes.

The apex-beat of the heart is in the fourth space and four inches to the left side of the midline. The cardiac thrust is *tumultuous* on palpation. The first mitral sound and the aortic second sound are both accentuated, especially the former. There are numerous *extrasystoles*. *These* have diminished with rest in bed. The radial artery is not palpable and the blood pressure is 140/100. The tonsils are healthy. The urine contains a trace of albumin but microscopically there is only squamous epithelium present. The non-protein-nitrogen is 35 mg. per cent., and the urea concentration and dye excretion tests are normal. The Wassermann reaction is negative. The electrocardiogram shows biphasic T waves in lead III., but is otherwise normal.

SUMMARY.

Two cases of unusual complications following diphtheria are recorded: (1) A *case of complete* heart-block persisting 18 years after the diphtheritic infection, and causing *practically no symptoms.* (2) A case of spastic hemiplegia following diphtheria and associated with *mitral regurgitation*. It is surmised that both the hemiplegia and the mitral regurgitation are due to an endocarditis occurring during the course of the diphtheria 11 years previously.

We are indebted to Dr. Eric Murphy (Birkenhead) and to Dr. de Boinville (Liverpool) for permission to publish Cases 1 and 2 respectively.

THORACOSCOPIC TECHNIQUE
INFLUENCED BY TYPE AND POSITION OF ADHESIONS.

By F. G. CHANDLER, M.D. CAMB., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL;
PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK.

IN a previous communication[1] the advantages of a single instrument for thoracoscopy and adhesion cutting, and the advantages of the diathermy current have been described. It is not to be thought, however, that it was claimed that these methods were necessarily the best in all cases. It is not entirely a question of one instrument or two instruments, of diathermy or the electrocautery, but what type of case is best suited to one, and what to the other. G. Maurer,[2] of Davos, for example, uses two instruments, and makes use of both the diathermy current for coagulating and the electrocautery for cutting, and his technique and his results are excellent.

There is little doubt, however, that the use of one instrument only is, in many cases, more easy and in a large number of cases very satisfactory. If it is found that the instrument has been inserted in a spot which makes access to the insertion of the adhesion awkward, even after careful localisation, as previously described, another diathermy electrode can easily be inserted through another cannula in another place, if this seems simpler than reinserting the operating thoracoscope. The 30° telescope would then serve as the source of illumination. The electrode can be a separate one, or the operating thoracoscope may be used as a simple electrode.

There is, however, one type of adhesion which is not well suited to the diathermy cutting wire, and that is the string adhesion. It offers great resistance. Even though it be cut well away from the parietal wall (which it is safe to do as it cannot contain lung), pain or the jumping phenomenon is experienced owing to the heat or an electric stimulus being conducted to the parietal insertion of the adhesion. The base, therefore, must be anæsthetised. Sometimes there are numbers of these adhesions. Each must be anæsthetised. This takes time. Each prick is felt. Oozing may occur from each prick; and when all is done the adhesion may be very difficult to cut owing to its resistance. All this can be avoided by using an electrocautery. If it is used a short distance from the pleura, no pain is felt. There is no danger from bleeding in this type of adhesion. The adhesion is severed in a few moments. For this reason I have had made a minute electrocautery which can be passed through the cannula, alongside the needle telescope, or rather in the groove between the flexibile shaft carrying the light and the telescope. A cable connects this to a small transformer which hangs on to the operating table and provides both the light current and the cautery current. The cautery can be pushed in and out and used at any desired distance from the end of the telescope. Thus a distant or close-up view can be obtained at will, and the best distance for working be secured. It is very easy to manipulate and has necessitated no modification nor further complication of the instrument. Cord adhesions can also be severed by this method the danger of bleeding being minimised, in the usual way, by keeping the cautery at a dull red glow. With large, broad, thick adhesions there are difficulties from smoke, smell, and bleeding if the electrocautery is used; these should be eliminated by the use of the diathermy current.

To summarise: for string adhesions, division by electrocautery appears to be the best method; for large adhesions, diathermy. Whether to use one instrument or two—that is to say, whether to do everything through one cannula, involving one puncture only, or through two cannulas—seems to depend on visibility and ease of access to the parietal insertion of the adhesion. Other things being equal I believe the one instrument method to have a number of great advantages. If the work can be done quite well through one puncture, why make two?

PROPOSED TUBERCULOSIS HOSPITAL FOR EAST GLAMORGANSHIRE.—Dr. T. W. Wade, of the Welsh Board of Health, recently held an inquiry at Cardiff into the proposal of the Welsh National Memorial Association for the erection of a new tuberculosis hospital at Hayes Farm, Sully. The medical committee of the Association recommended that two hospitals should be provided, one for Swansea and the western side of Glamorgan, and the other to meet the urgent demands of Cardiff, East Glamorgan, and the adjoining area. It is calculated that the capital expenditure on the hospital during the next two years would be £125,000, exclusive of expenditure on land. The number of beds it is proposed to provide is 250 with future extensions to 300 or 350. The inspector will make a report to the Ministry of Health.

CLINICAL AND LABORATORY NOTES

THIRTY-EIGHT YEARS WITH A FRACTURED SPINE.

BY DOUGLAS GREEN, M.B. LOND., F.R.C.S. ENG.

THE unusual length of the period of survival after sustaining a fracture of the spine seems of sufficient interest to warrant publication. Perhaps some of your readers can answer my contention that the case is unique. During my student days it was generally taught that the maximum expectation of life after such an injury was two years, while the average was much shorter. Only recently I treated another man who lived over 12 years, after being thrown from his horse and sustaining a fracture of the spine through the twelfth dorsal vertebra.

The present case was somewhat similar. On August 8th, 1892, a telephone linesman, then aged 21, fell from a high telephone pole and fractured his spine between the eleventh and twelfth dorsal vertebræ, After a stay in hospital he was sent home and was attended by my predecessors in this practice. On my first making his acquaintance he was living in a spinal carriage with complete paralysis of both legs and lower abdominal muscles. Contraction of the muscles had taken place with the result that the legs were stiff, the hips being in normal position to the body in the supine position, the knees extended, and the ankles and feet in extreme talipes equino-varus with large corns over the external malleoli from friction of the bedclothes. Nursing was carried on by his sister, some eight or nine years older than himself, and no bed-sores appeared in the whole period he was under my observation. Naturally he had incontinence of urine and fæces and suffered from cystitis. He washed out his bladder daily with a weak solution of Condy's fluid, using an ingenious syphon arrangement attached to an ordinary rubber catheter.

Twelve months ago a perinephritic abscess appeared in the right loin. This was incised without the necessity of an anæsthetic and has since discharged urine and pus through a small sinus, urine also draining per urethram. Death finally ensued on March 9th, 1931, through renal insufficiency due to pyelonephritis secondary to cystitis, the man then having just reached his sixtieth birthday.

Sheffield.

RECURRING HERPES GENITALIS IN THE MALE.

ÆTIOLOGY AND TREATMENT.

BY J. AVIT-SCOTT, M.D. BIRM.,
HONORARY DERMATOLOGIST, MIDLAND HOSPITAL, BIRMINGHAM.

RECURRING herpes genitalis in the male is one of those minor ailments which besides being a great nuisance to its unfortunate owner, opens the door to much more serious infections like syphilis and soft chancre. The diagnosis is quite easy, and the disease so common that no full description is needed. When seen early the lesions, which are generally found in the balano-preputial groove, appear as a cluster of small rounded vesicles, the size of a pin's head and containing a clear fluid. Later they appear as a cluster of shallow circular erosions which are not indurated if they have not been irritated by caustics or other forms of unsuitable local treatment. The lesions are rather *irritating* and slow to heal considering their small size, but the irritation is as a rule most intense for a day or two before the vesicles appear. The consensus of opinion is that the condition is due to a filter-passing virus, and its frequent association with chronic venereal conditions of the genital tract, which had been noted by Doyon and Diday, suggested to me a method of treatment, and after effecting a cure in 12 cases I am of the opinion that in the majority of cases the condition is due to the presence of septic foci in the prostate.

I had noted during the war in France that prostatic massage in cases of chronic prostatitis often brought about an attack of herpes genitalis in patients, whether they had previously suffered from the condition or not, and I noted also that the cure or improvement of the prostatic condition led to an apparent disappearance of the herpes. Herpes genitalis often follows extra-conjugal intercourse or excessive coitus, which may be the equivalent of a powerful prostatic massage and shake up the infected foci. I do not know if excessive coitus or massage of the prostate releases a filter-passing virus which acts on the nerve-endings in the balano-preputial groove, but the following line of treatment has proved successful in these cases.

In all cases of recurring herpes genitalis, whether they suffer from a gleety discharge in the morning or whether they have threads in the urine or not, my procedure is as follows:—

(1) The possibility of stricture is settled by passing Nos. 7, 8, 9, 10, 11, 12 gum elastic bougies; if there is a stricture it may take several weeks to reach No. 12, and during this period hexamine. grs. 10 with tr. hyoscyamus ♏xx. three times a day before meals, is given in a small tumblerful of water.

(2) When a free flow of urine has been established the prostatic massage is commenced, which must be gentle at all times, but especially at first when the prostate may be acutely tender. The patient is instructed to hold his water for two hours before coming to me, when he is asked to pass a few ounces of urine in a conical glass, and the state of affairs in a case of threads or gleet is noted—then massage is performed gently on a bladder still partly full, after which the patient is instructed to empty his bladder completely.

(3) After the third prostatic massage which is repeated at intervals of a week, I begin instillations with weak solutions of silver nitrate. The patient after massage empties his bladder and by means of a small flexible acorn catheter size about 7 or 8 (French) fitted on the nozzle of a 1 c.cm. hypodermic syringe and the whole apparatus filled with the solution, a few drops of the silver solution in instilled in the prostatic urethra and also along the anterior portion of the canal. It is generally quite safe to start with a 1 in 3000 solution of silver nitrate. If the patient does not experience any undue desire to micturate after this and is able to hold his water for two hours or so, the next time I generally use a solution of 1 in 2500 and so on up to 1 in 500 if necessary, but 1 in 1000 which may be repeated several times is generally the maximum strength required. This is the treatment of prostatic gleet, and a very successful one too, if it is remembered that

no force is required in massaging the prostate and that instillations with strong solutions of silver nitrate do more harm than good.

After three or four weeks of treatment by massage followed by instillations one finds that the prostate, instead of being tender all over, is only tender over certain areas and then I massage gently over those spots which the patient indicates to me. The local treatment of recurring herpes genitalis consists in not irritating the lesions; the parts should be cleaned with warm water, dried carefully, and dusted freely with pure talcum powder. During the treatment of two cases I had curious experiences. One patient developed a typical eruption of herpes zoster affecting the left buttock and left thigh down to the knee, and as this form of herpes is considered to be of a different nature than the one we are now considering, the occurrence was probably a curious coincidence. The second patient was relieved from a mild but generalised pruritus of over 12 months'standing which I intended to deal with at a later date.

As a dermatologist I attach more importance to a prostate which feels what may be called normal, and is free from pain and lumps on massage, and to the absence of heavy sinking threads in the urine than to the presence of a few pus cells and a few fine floating threads in the urine, which may be due to a superficial catarrhal inflammation of the mucous membrane, as a rule clearing up completely in a month or two in the absence of over-treatment.

MEDICAL SOCIETIES

OPHTHALMOLOGICAL SOCIETY.

ANNUAL CONGRESS.

THE annual congress of the Ophthalmological Society of the United Kingdom took place at University College, London, from April 23rd to 25th, under the presidency of Mr. LESLIE PATON. Among numerous papers contributed was one on

Non-luetic Argyll Robertson Pupil

by Mr. R. FOSTER MOORE. It recorded eight additional cases since his paper on the subject in 1924. Twelve of the total 15 cases were in females, so the condition could be said to be commoner in the female than in the male sex. He could not be definite about age incidence, since a number of the cases were discovered quite by accident, some had not been known to the patient, and in none was the date of onset accurately known. Some might be congenital, though in only one case was it suggested that the condition had been present ever since birth. The ages of onset given ranged from birth to 42. In 14 cases the fundi were examined with the aid of a mydriatic, but in none was any important abnormality discovered. The visual acuity did not seem to be affected; in 14 cases it was 6/6 in each eye after correction. The condition was usually unilateral and the pupil might be described as semi-dilated. It was practically inactive to the light stimulus, whether direct or consensual. Contraction occurred with convergence, but the rate of such contraction varied much, as also did its completeness. There was always a slow relaxation. Accommodation was not paralysed, and Mr. Foster Moore did not think the ciliary muscle was involved. It was important, he said, to discover whether these pupils bore any relation to syphilis in the patient, or whether any general nervous disorder coexisted. In none of this series was there a history of syphilis, or discovered syphilitic lesion. In two cases there was a slight drooping of the upper lid.

Leber's Optic Atrophy.

Dr. RITCHIE RUSSELL (Edinburgh) read a paper on Hereditary Aspects of Leber's Optic Atrophy. This disease, he said, did not seem uniformly to follow the rules of inheritance of a single recessive character. In Leber's disease an affected male rarely had affected grandsons. The mode of inheritance was not the same in the various sex-linked diseases, and in some strains at least an accessory factor was concerned in their development. Dr. Russell's paper dealt with four cases in the same generation in a family living in the Orkneys.

The first patient, a man aged 40, had loss of vision and pains in the legs. At first there was only slight dimness of vision after reading; it did not interfere with his work as a carpenter. Later he had severe pains in the right eye, which lasted a week, and with these pains the vision failed rapidly in both eyes. Coincidently he had pains in both feet, and they became swollen. Vision had improved but little. He had five healthy children. Higher cerebral functions were apparently undisturbed. Both the discs were blue-grey in colour; the edges were sharply outlined, and the lamina cribrosa was prominent. No changes were apparent in the maculæ or the periphery of the retinæ. The pupils were 4 mm. in diameter, circular, equal, and regular in outline. Ocular movements were full in all directions. Neither nystagmus nor diplopia was present, but the patient could not converge. No disturbance of muscle power, tone, or coördination was noted; neither was there any abnormality to light touches, to pain, or appreciation of passive movement.

The other cases were somewhat similar, with variations. Three cases in the generation followed a consanguineous mating; probably the original stock bore a trait of the malady. Perhaps a second factor, not sex-linked, and multiplied by the consanguinity, was concerned in the manifestation of the disease. Dr. Russell did not think this likely, but the consanguinity might have reduced the general vigour of the stock and so caused a dormant trait to become manifest again. Leber's disease showed no evidence of its presence until years after birth; and in this it stood alone in this group of diseases. It could be classed as an instance of inherited tissue vulnerability.

Mr. A. W. ORMOND read notes on

Ocular Symptoms in Osteitis Deformans.

The case he described was reported by Dr. Herbert French in 1920, and eight years later Mr. Ormond saw him because of his ocular condition.

The first complaint had been of pains in the right tibia, followed by pain and aching in all bones. A curvature of the radius was noted, and at a later stage there was pain in the head bones. He had not had typhoid fever, nor lived abroad, there was no history of syphilis, and he was an abstainer and non-smoker. Early in the illness he complained of a flickering to the right in his eyes, and he tended to move to the right instead of straight ahead. Vision in the left eye was defective; and he could not see with it unless he looked towards the ground. When Mr. Ormond saw him there were definite pathological changes in the fundus of the left eye involving the macular area. Vision of the right eye at that time was 6/6, but that of the left was less than 6/60, and there was only peripheral vision. A large choroidal hæmorrhage was seen, with much disturbance of retinal pigment. Later there was much failure of vision in the right eye, and similar changes to those in the left, the visual acuity being no more than 6/36.

This year the patient could not see 6/60 with either eye, and central vision was very depressed. In the right eye was a large mass of organising tissue in the macular area. There was also, in this neighbourhood, a scattered patch of probably old hæmorrhagic pigment. The left macular region was occupied by an atrophic area, with sclerosed and tortuous choroidal vessels; the arteries were small and attenuated. There were gross changes surrounding the optic disc. The hearing power was lessening.

It was clear, Mr. Ormond said, that the ocular defects which had been reported in association with Paget's disease were due to two separate conditions: (1) changes caused by the optic foramen pressing on the nerve and leading to changes in the fields of vision, with loss of visual acuity and the production of optic atrophy, &c.; (2) definite retinal and choroidal disturbance with hæmorrhages the result of widespread vascular changes which did not affect the nerve head at all. Many observers had found in the eyes of patients suffering from osteitis deformans a condition similar to that found in advanced disease consequent on inherited syphilis. Tubby had stated that the disease was probably a disorder of the perverted metabolic type. In one recorded case marked improvement followed a change from a partially carbohydrate to an almost exclusively protein diet. With the diagnostic aid of improved radiography the disease did not appear to be as rare as was formerly supposed.

The general weight of opinion seemed to be that a toxin or some chemical deficiency, acting through the blood stream and affecting the vascular system generally, was at the root of the matter. Most cases of long standing had some evidence of vascular changes, both in the fundus oculi and in the body generally.

Treatment of Detached Retina.

Mr. C. SHAPLAND contributed a paper on A Hundred Cases of Retinal Detachment Treated by Cautery Puncture. He said that in December, 1929, Sir William Lister carried out the first operation in Moorfields Eye Hospital according to Gonin's method for retinal detachment, and since then 100 cases had been so treated. This operation presupposed that a hole in the retina had been discovered, and an effort was made to occlude it by a cautery puncture. Fifty-six of the patients were males, 44 females, and the average age was 41½ years. Refractively considered, there were four groups: high myopes, low myopes, aphakics, and emmetropes. Thirty-two patients had a myopia of more than 5 D, 24 less than this, three had aphakic eyes, and in 41 the refraction was either emmetropic or slightly hypermetropic. Trauma (local or general) seemed to have been an ætiological factor in a small proportion of the myopic detachments, and a much larger proportion in the emmetropic group. In the 56 cases of myopic detachment, nine had a blow on the affected eye or adjacent part of the head immediately before the visual defect occurred. In a case of bronchitis the coughing seemed to have precipitated the detachment. In the emmetropic cases 16 gave a history of recent local injury.

Retinal holes could be put into five groups. The commonest site for a retinal hole was the periphery of the temporal half of the globe. Disinsertions showed a marked preference for the emmetropes; 66 per cent. of the rents were at the ora serrata, while they occurred in 25 per cent. of the low myopes, and only 9 per cent. of the high myopes.

Forty of the 100 cases were discharged from the hospital cured, and 17 others showed improvement, either in visual acuity or the area of the field. The average age of the cases cured—both sexes—was 34½. The average duration of the detachment, from the time of onset of the visual symptoms in the affected eye to the date of admission to hospital for operation, was seven weeks, the longest duration after which a successful result was attained being 12 months, and the shortest, seven days. In the aphakic group no successful result was obtained. The round-hole cases afforded the best prognosis, 53 per cent. of these being cured; disinsertion cases gave 49 per cent. of cures. Of the 40 primarily successful cases, recurrence of the detachment took place in 11, the interval varying between a week and eight months. In 30 of the total cases the restoration had remained in situ—for 15 months in the earlier cases.

Vitreous hæmorrhage at the seventh to tenth day after operation was the worst sequel when the Paquelin cautery was used, but after this was supplanted by the electric thermo-cautery this complication had been practically absent. There were four cases of fairly severe uveitis, two of traumatic cataract, and two of subretinal hæmorrhage. No eye in the series was lost through panophthalmitis.

The PRESIDENT spoke of the importance of this treatment for what had formerly been looked upon as a very hopeless condition, so that ophthalmic surgeons were taking up this line of attack with great hopes of success. Yet in early days successes could be recorded. In 1906 he operated upon a lady for a detachment which caused blindness in the eye, and the last time he saw her, 24 years later, she was seeking a licence to drive a motor-car. Another patient, whose vision had been reduced to mere perception of hand movements, shot, some time after the operation, 22 partridges and a rabbit with 24 cartridges.

Mr. FRANK JULER mentioned a series of his own cases of detachment which he had treated by the Gonin procedure. He had had 32 per cent. of cures. One case was that of a man aged 50, whose vision before the operation was reduced to hand movements on the temporal side. After the Paquelin cautery applications both the field and the vision were improved at once. The retina was in place up and in, but was still detached below. Another small hole was detected in this area, and eight and a half months after operation the retina was in place throughout, and the visual field was full. The other case was one of bilateral detachment of old standing in a man aged 27. Operation resulted in a vision of 6/24 in the right eye, 6/5 in the left, the fields were full, and the retinæ firmly fixed.

Chronic Blepharitis.

Mr. M. S. MAYOU submitted a contribution on Treatment of Chronic Blepharitis with Vaccine. The condition, he said, varied in severity from the seborrhœic type—in which a small amount of discharge stuck to the lids, with a slight desquamation of the epithelial cells at the lid margin—to severe ulcerative blepharitis with destruction of the lid margin, hair follicles, glands, &c., and thickening due to the chronic inflammation of the lid. The milder forms were easily remedied by using the customary staphylococcal vaccine and the local application of lotions and ointments such as yellow oxide of mercury and resorcin. His purpose was to speak of the treatment of the more chronic type, which gave rise to trichiasis and tylosis, with eversion of the puncta and ectropion. Infection of the conjunctiva was always present. In the first instance the infection was staphylococcal, derived from the glandular secretions of the lid margin, but, sooner or later, there was usually an infection with the Morax-Axenfeld bacillus. Usually there was an accompanying eczema of face and head. It was important at the beginning to get rid of any source of septic infection, such as tonsils, or to deal with discharging ears, and to give appropriate tonic treatment, with sunlight, cod-liver oil, and, if necessary, glasses. Considerably improved results ensued at the Swanley institution by injecting a mixed vaccine of staphylococcus and Morax-Axenfeld bacillus into the eyelid. It was of the strength of 500 million to 1 c.cm. of each organism. If cases did not respond to this, they did to an autogenous vaccine. The treatment was continued once a fortnight until a cure ensued. When patches of ezcema were associated with chronic blepharitis, injection of vaccine under the patches had often cleared up those areas, even when they had existed for years and had not yielded to any other form of treatment.

One session was set apart for a discussion on

Affections of the Eye Due to Viruses.

Dr. J. R. Perdrau, in opening, said that the terms ultramicroscopic and filtrable were not applicable to viruses as known to-day. So long as the agent responsible for a disease remained undiscovered, it could not be spoken of as the virus of that disease. He entered into a consideration of the better known characters of viruses, and a comparison of them with visible bacteria. The mere fact that the causative agent of any particular disease passed through one of the filter candles in common use did not justify its inclusion among the viruses, at least until the conditions of filtration had been standardised. Certain virus diseases were characterised by the presence of inclusion bodies in one or more organs or tissues. Some, such as the Negri bodies of rabies, were highly characteristic, and important for diagnostic purposes. Inclusion bodies had been produced in the rabbit's cornea by physical agents, such as ultra-violet rays. An important negative character of viruses was that, up till now, it had been impossible to cultivate them on lifeless media. There was often a close association between viruses and the cells of the tissue or organ in which they multiplied in the living animal. This had proved to be a very important factor in the experimental study of viruses, particularly in regard to problems of infection and immunity in their broadest sense. Dr. Perdrau proceeded to speak in detail of the study which had been made in regard to the viruses of vaccinia and herpes; also on species specificity and tissue specificity in relation to immunity.

Mr. F. T. Ridley devoted his attention to some diseases of the eye which were known to be due to viruses, with some reference to the viruses which attacked the eyes of animals. The virus of vaccinia inoculated on the cornea of a rabbit caused a lesion similar to the vaccinial pustule on the skin. Hypopyon was frequently seen. The acute condition subsided, leaving opacity of the substantia propria and permanent scarring. There was a generalised immunity to reinfection with the virus of vaccinia. In herpes febrilis keratitis the lesion started as a localised opacity in the substantia propria. This might so spread as to involve the whole cornea. Perdrau's virus, obtained from lungs of patients dying of pneumonia, produced very severe keratitis, usually involving the whole cornea. It was accompanied by great vascularisation. Mr. Ridley spoke also of dendritic ulcer, which, he said, might arise in several ways. In many cases it arose in association with malaria, and in these it was relieved by administering quinine.

Mr. F. A. Williamson-Noble thought that in the case of the herpes virus infection a very important factor was the resistance of the patient or the local resistance of the part affected. As to the pathology of herpes zoster, Head and Campbell's description in 1900 still held good. The virus caused an acute inflammation in the Gasserian ganglion, and this was accompanied by hæmorrhage, the eventual condition being a fibrosis, with thickening of the overlying sheath. In severe cases the virus spread so as to implicate other nerves. Treatment was mainly symptomatic, but Friedenwald had reported the result of treating such a case with convalescent serum. Coincident iritis proved to be resistant, but eventually the vision rose to 6/9. Speaking of sympathetic ophthalmia, which Mr. Williamson-Noble thought might be due to virus infection, he said that Sommer had described two cases of sympathetic ophthalmia following herpes zoster, though in both those patients there was perforation of the globe. Both eyes showed the histological changes of sympathetic ophthalmia. Szily had stated that the clinical picture produced by the herpes virus suggested that sympathetic ophthalmitis might be caused by a virus, so far undiscovered, which passed from one eye to the other by means of the sheaths and chiasma of the optic nerve. If this were true it was important when considering the question of removal of the exciting eye; the optic nerve should obviously be severed, and as far back as possible.

Dr. L. H. Savin spoke of two cases in which he thought a virus was responsible for the activation of other organisms. One was a case of cavernous sinus thrombosis which followed nine days after injection of a vaccine for rheumatism. The patient had swollen eyes and face and a temperature of 105° F.; a blood-stained fold of conjunctiva protruded between the right lids, and both eyes were blind. The blood showed 20,000 whites, 90 per cent. being polymorphs, and 8 per cent. lymphocytes. There was a complaint of headache and pain over the eyes. Cavernous sinus thrombosis was diagnosed, and on the fifth day of the illness the boy died. Streptococci were isolated from pus at the base of the brain. He was probably, as shown by his rheumatism, specially sensitive to streptococci.

Mr. Humphrey Neame spoke on keratitis in dogs in association with distemper and other conditions, and the discussion was further continued by several members.

Air Vice-Marshal Sir David Munro read a paper entitled

Vision in Sports and Games.

The visual factors, he said, were not the only ones concerned in proficiency in games; good muscular coördination and kinæsthetic sense were as necessary as good visual judgment. Instructors should not attempt to train on the motor side until the perceptive side had been investigated, the latter to include the causes of faulty visual judgment. There was a tendency to instruct to a set pattern, apart from personal peculiarity. He classified sports and games into: (1) those in which the player had to follow with both eyes the flight of an approaching or receding ball and to judge its pace; (2) games, such as golf and billiards, in which the ball had not to be followed, but a stroke had to be timed and executed with delicacy; (3) shooting sports, in which the flight of an approaching or receding object had to be followed with both eyes, and accurate timing carried out; (4) the monocular sport of shooting with a rifle at a target; (5) rifle shooting at a moving target; (6) motoring and flying, in which the judgment required was that of one's own pace. The chief visual judgments to be made in games concerned pace, space, and place.

There was a good deal of evidence that imperfect ocular balance was important in causing deficient following of a moving object binocularly, so causing erroneous judgment of distance. The speaker concluded his paper by saying that if he were intending to specialise as a teacher of ball games he would rely on his amblyoscope and stereoscopic charts for correcting the chief sources of visual error.

Papillœdema.

Mr. EUGENE WOLFF (in collaboration with Mr. FRANCIS DAVIES) read a report of work carried out in the Anatomy Department of University College, London, on the Pathology of Papillœdema. The conclusions arrived at were: (1) Non-diffusible dyes injected into the cranial subarachnoid space, at pressures which are compatible with life, do not enter the optic nerve. (2) Claims to have produced papillœdema by injecting fluids into the subarachnoid space at pressures compatible with life were not upheld by this study. Structural reasons were advanced for the special site of commencement of papillœdema in human beings, and for the extent of the distribution of the œdematous fluid associated with papillœdema.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.

A MEETING of this society was held at the London Jewish Hospital on April 16th, with Dr. LEOPOLD MANDEL, the President, in the chair.

A paper on modern advances in the

Diagnosis of Intracranial Tumours

was read by Dr. GORDON HOLMES. As tumours might occupy any region of the brain, he said, all possible signs of neurological disorder might be produced. Localisation was always interesting, for it could be checked by the surgeon. Treatment had not advanced in the same way as diagnosis and localisation, for 60 to 70 per cent. were gliomata, or spreading tumours, and therefore difficult to extirpate surgically. Herein lay a possible advance in treatment by X rays or radium. The diagnosis of tumour was made by the presence of increased intracranial pressure, evidence of local disease, and symptoms of irritation. Increase of intracranial pressure was brought about either by the size of the tumour itself in the closed cranial cavity, by reactionary changes around the tumour (especially malignant metastases), or by interference with the circulation either of blood or cerebro-spinal fluid. Headache, vomiting, and optic neuritis were the classical signs, but any two of these were sufficient to make one strongly suspect its presence. The diagnosis became certain, when besides increase of pressure there was disturbance of function (depending on the site of the tumour) pointing to local disease; this was usually of slow and gradual development. Irritative phenomena might take the form of local epileptiform seizures, of which tumour was the commonest cause. These sudden disturbances might be brought about either by reaction around the tumour, hæmorrhage into the tumour, or extension involving new structures, or obstruction of the flow of cerebro-spinal fluid—e.g., in the aqueduct of Sylvius.

The signs of cerebral tumour must be differentiated from those of: (1) primary degenerative changes, where there was no rise of pressure, and the lesion was diffuse and bilateral; (2) chronic uræmia, which could be diagnosed from an examination of the urine, blood-vessels, and blood pressure; and (3) cerebral arterio-sclerosis. The mathematical accuracy of localisation was interfered with by disturbances of other parts of the brain by such factors as displacement and the increase of pressure, but in spite of this, by clinical methods alone 80 to 90 per cent. could be localised. Dr. Gordon Holmes drew special attention to disturbances of sensation and of vision with tumours of the forebrain. There was no marked disturbance of cutaneous sensation, but discrimination was affected—that is, the sense of position of the limbs, stereognosis, and the recognition of simultaneous contact of two points in the compass test. As regards visual sensation, there might be gross disturbance of the fields, such as homonymous hemianopia, but on careful examination other disturbances might be found—e.g., visual inattention on the simultaneous exhibition of two objects (in superficial lesions of the parietal and occipital lobes), or visual disorientation (especially in lesions of the left side of the brain).

Recent advances in aids to localisation had proved of little true value. X rays were occasionally useful, but the interpretation of the skiagram was difficult. Pneumo-encephalography was attended by an 8 per cent. mortality, and the more careful the clinician the less use there was for this method. Injection of the carotid artery with sodium iodide solution was dangerous. Auscultation of the skull with the ear, by the presence of a murmur might reveal a vascular tumour or aneurysm; whilst percussion over the skull might reveal a tender area over the tumour. The important point to be remembered was that time and repeated examinations may be necessary before the tumour could be definitely localised.

Mr. JULIAN TAYLOR read a paper on the results of the

Surgery of Intracranial Tumours.

Compared with many other branches of surgery, intracranial operations presented a high mortality, a depressing proportion of complete failures, and of cases where only some of the symptoms were relieved. In contrast there was a small proportion where complete success was attained and a larger where disease was arrested and patients returned to nearly normal health. The variability of the results and the undoubtedly high proportion of failures and partial failures, was to be accounted for by the large number of conditions for which cranial operations were undertaken and by the complexity of their effect on the brain. Percentages were useless in estimating the prospects of a particular case, and to make a prognosis the following seven questions must be answered:—

1. Is the tumour of such a nature that it can be removed by operation or destroyed by irradiation?—Most intracranial tumours were malignant infiltrating neoplasms not associated with secondary growths. Some 60 per cent. were gliomas which infiltrated the brain but not its coverings. Their malignancy varied and their growth might sometimes be completely arrested. Only a very small proportion appeared to be amenable to treatment by irradiation at the present time. Some 12 per cent. were endotheliomas ("meningiomas"), which displaced the brain but infiltrated its coverings. Their malignancy was practically constant and their infiltration was so slight that in practice it might almost be neglected. The remainder were for the most part benign—pituitary, acoustic, congenital, and angiomatous tumours.

2. Is the tumour neurologically localised with sufficient accuracy?—A very high pitch of accuracy could be reached, but certain knowledge either of position or of size was not necessarily available.

The visual means by X rays, with or without air injection, lagged far behind.

3. Is the tumour in an accessible place and is it wholly accessible?—Examples of tumours at present partly accessible were subcortical tumours growing deeply towards the corpus collosum or basal ganglia.

4. Has it already destroyed the neighbouring brain so as permanently to abolish function?—Most intracranial tumours, when they presented themselves for operation, the neurological signs and symptoms were due more to temporary vascular effect of the growing tumour than to actual destruction, so that removal of a tumour or decompression might result in recovery from symptoms. The visual paths and cortex were exceptions and rarely showed signs of recovery.

5. Has the tumour already caused so great a rise of intracranial pressure as to make removal extremely difficult, extremely dangerous, or impossible?—In spite of the high level attained by neurological diagnosis, a large number of cases presented themselves with high intracranial tension which placed the greatest difficulty in the way of surgical relief. Methods were available for mitigating this danger. Where papillœdema had resulted in atrophy, return of vision was not to be expected.

6. Are there difficulties special to the tumour?—There were difficulties special to most tumours—e.g., tumours in the neighbourhood of the left Sylvian fissure or of the left motor cortex were rarely susceptible of removal on account of aphasia and right hemiplegia. Tumours in the posterior fossa were dangerous on account of hæmorrhage from cerebellar vessels and of the proximity of the medulla, which prevented any but the slightest manipulation.

7. In the likely event of an unfavourable answer to any of the six preceding questions, is a measure of relief possible or can palliation be achieved?—For decompression to produce relief, it must be over the tumour. Where there was hydrocephalus, decompression might give little relief, especially in the posterior fossa. The site of obstruction to the cerebro-spinal fluid pathway, whether on its outward or return flow, was an important factor in the posterior fossa. Decompression either above or below the tentorium was rarely beneficial in tumours obstructing the incisura tentorii.

Mr. Taylor concluded by giving a short résumé of results in glioma, endothelioma, pituitary, acoustic, and hæmangiomatous tumours. In gliomata the results were doubtful—i.e., variable. In endothelioma the progress depends on size and length of time preceding the increase of intracranial pressure; recurrence in the coverings was unfortunately too frequent. Pituitary tumours in some cases could be successfully operated on, but deep X ray therapy seemed to hold some hope. More knowledge of this form of therapy was awaited. Diathermy in the removal of some growths had met with success.

The PRESIDENT said that members of the society, having heard the two speakers, would in future approach cases of growth of intracranial cavity with a little more optimism than hitherto.

Mr. H. S. SOUTTAR pointed out that the symptoms displayed by the patient were often quite out of proportion to what was found at operation. A very small tumour might give rise to an immense hydrocephalus, whilst on the other hand he had had a case in which a huge tumour of the parieto-frontal region caused no symptom except extreme cheerfulness.

Dr. M. SCHWARTZMAN gave details of a case of pituitary tumour alleviated by radium.

Mr. S. I. LEVY recorded a case of cerebral sarcoma, treated by radium after decompression; the patient had lost his symptoms and was now carrying on a normal life.

Dr. GORDON HOLMES, in reply, thought there was a future for X ray therapy in certain types of tumours. With radium, the results at Queen-square had so far been disappointing.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

AT a meeting of this society at Liverpool, on March 20th, Mr. ST. GEORGE WILSON read a paper on

Lower Uterine Segment Cæsarean Section.

He reported the result of 50 of the 54 cases of which full details were available and in which he had used this incision. Twenty-three patients were primiparæ, 27 multiparæ, and 15 had had previous Cæsarean sections. In 22 of his cases there was general contraction of the pelvis and in 14 flat pelvis. There was one case of oblique contraction and one of disproportion, which Mr. Wilson agreed with Mr. Leyland Robinson in ascribing mainly to deflection of the head due to or associated with imperfect functioning of the uterus. Pelvic tumours were present in four cases. In two cases operation was done on account of cardiac condition. The remaining five comprised three patients with bad obstetrical histories, one with prolapse of the cord, and one elderly primipara with a breech presentation and rupture of the membranes of four days' duration.

The lower uterine segment incision, said Mr. Wilson, extended the indications for operation. He thought that it also tended to diminish the number of operations performed. The text-book measurements of the pelvis were, he thought, well above normal and a large number of cases labelled "generally contracted pelvis" would deliver themselves if given the chance of a trial labour. His operation-rate at Walton Hospital was 1 in 14·3 deliveries. The average duration of labour in his 50 cases was 15·3 hours, the period of labour allowed being regulated by the condition of the fœtus alone. The longer the labour the simpler the operation. Reported cases showed that the morbidity-rate was greater in classical than lower segment Cæsarean section. The speaker agreed with Munro Kerr that the uterine wound was infected from the interior by an ascent of bacteria from the vagina. In his own series, excluding six cases of pulmonary condition and one of pyelitis, five were notifiable under the pyrexia Act, a morbidity-rate of 10 per cent. The average stay in hospital was 19·4 days.

Besides its immediate importance, he considered that sepsis had a bearing on future pregnancies and labours. He thought, however, that the situation of the placenta over the previous scar was the important ætiological factor in five of the six cases of rupture he had reported to the society. It was stated that the placenta was attached to the anterior wall in 40 per cent. of pregnancies. Apart from the absence of placental attachment, the lower segment had the advantage that it bore no stress during pregnancy or early in labour when rupture was most likely to occur in the classical scar.

Among the children there was one stillbirth, a hydrocephalic with spina bifida, and two neonatal deaths, one soon after delivery, the other at ten days from gastro-enteritis.

A film of the operation was then shown and described. A catheter is kept in the bladder till the patient was put on the table. The position used is a moderate Trendelenburg.

The abdomen is opened by a mid-line subumbilical incision and a large Doyen retractor introduced. After careful packing off, a curved transverse incision is made as low down as possible in the utero-vesical pouch. The bladder is not pushed down and a similar curved transverse incision is then made through the lower segment, the lateral extensions of the incisions being made with scissors. Pressure on the fundus forces the head down and delivery is assisted by means of one blade of Simpson's forceps used as a vectis. Traction on the head then completes delivery. The placenta as a rule separates at once and is delivered by traction on the cord. At this stage an injection of ergotamine phosphate and histamine is given intramuscularly. The incision is then closed by continuous catgut sutures in two layers, the decidua being avoided and the cut edges inverted. A third continuous suture closes the peritoneum. Graf's No. 3 catgut is used throughout.

Mr. Wilson said he had never left the placenta to be delivered per vias naturales. In conclusion he referred to the easy convalescence of these cases, the absence of intestinal complications, and the advantage of confining any infection to the pelvis and behind a loosely attached peritoneum rather than allowing it to spread through the adherent upper-segment peritoneum to the higher parts of the abdominal cavity.

Prof. Blair Bell showed a uterus with attached portion of colon removed at operation for a uterocolic fistula due to carcinoma. He also described a case of intra-uterine pregnancy occurring after conservative operations for different lesions first on one tube and later on the other.—Prof. Blair Bell and Mr. Leyland Robinson each described cases of fibromyomatous uteri simulating pregnancy.—A specimen of torsion of a hydrosalpinx was demonstrated by Mr. N. L. Edwards (Derby) and Mr. St. George Wilson showed a uterus which had spontaneously ruptured during unassisted delivery of the child.

LIVERPOOL MEDICAL INSTITUTION.

At a meeting of this institution on April 16th, with Prof. W. Blair Bell, the President, in the chair, a discussion on the care of

The Child from Birth to School Age

was opened by Dr. Leonard Findlay (London). Although infant mortality had improved considerably during the last 30 years it still remained, he said, a very serious problem. Until 1913 the death-rate was higher in England than in Scotland, but since then the reverse had been the case. One of the chief reasons for this reversal was the relative disappearance of epidemic enteritis, which was always more severe in England owing to climatic conditions. However, the simultaneous fall in deaths from this cause in various towns in Britain, Europe, and America suggested that the disappearance was in response to natural laws rather than as the result of any human efforts. Measles and whooping-cough were responsible for a large proportion of infantile deaths, and he suggested that one method of combating these diseases would be the provision of housing accommodation in order to lessen the density per unit area of the population, thus decreasing the opportunity for the spread of the infection. He agreed that the relatively more rapid fall in the infantile death-rate in England might be partly due to the intensive child welfare movement there, and quoted the fact that in England the deaths from convulsions and debility had fallen 200 per cent. since 1911, whereas in Scotland the fall amounted to 25 per cent. at the most. He emphasised, however, that there must not be too much supervision, or at least ill-directed interference with nature—a prevailing state of affairs as suggested by the rise in deaths from injury at birth, and rendered still more probable by the simultaneous increase in maternal deaths. Between birth and school age environmental conditions exerted their greatest effect. Tuberculous infection was then most prevalent and deaths from tuberculosis were more numerous during the first year than during any single year thereafter. It was difficult to estimate the amount of tuberculosis contracted during early life, for often it did not declare itself until later, but it was known that much of it was due to the bovine tubercle bacillus transmitted by milk, and consequently preventable. He urged, therefore, that no efforts be spared to secure a pure milk-supply. The provision of tubercle-free milk must apply to rural districts as well as to the large cities, for there was good reason to believe that bovine tuberculosis was relatively more prevalent in rural districts and small towns.

Dr. Norman Capon quoted figures to show that, in spite of the gratifying reduction in the infantile death-rate during the present century, there had been only a slight fall of mortality-rate during the first four weeks of life. Every new-born baby still passed through a period of great danger to life; and when he survived he might have suffered damage which would jeopardise his future. It was an appalling fact that 47,868 infants died in England and Wales during 1929 before they reached the first anniversary of their birth, and that 21,136 of these babies did not survive the neonatal period. During the same year the total maternal deaths numbered 2787. Close coöperation was needed between obstetricians and pædiatricians. The former were in a position to employ prophylaxis when it might reasonably be expected to be most fruitful. It could be divided—to quote Eardley Holland's happy phrase—into the strategy of obstetrics (antenatal supervision) and the tactics of obstetrics (conduct of the labour).

Dr. H. R. Hurter said that the healthy child of 4 or 5 needed better exercise than the long monotonous walks alongside the perambulator of his younger brother; outdoor games and the garden sand-heap were favoured. He thought the incidence of measles amongst Liverpool's middle classes would be lessened if the annual civic children's party were held in May or June instead of in January. Dr. Hurter said that acidosis had become too fashionable a diagnosis. Parents had now the same dread of this word that the whole nation had of the term "blood pressure" less than a generation ago.

Dr. A. Dingwall Fordyce said the modern conception of medicine was wide, and so far as the care of the young child was concerned could be considered as composed of purely physical care and of mental care, with the very important inclusion of wholesome neglect. The object in early years must be to preserve normality, and rational care must be under medical supervision. A unified medical service was necessary, and in order that such service be capable and reliable undergraduate instruction in pædiatrics must be developed.

The President said that he had long been of the opinion that obstetricians should surrender the care of the child from the hour of birth to the pædiatrician. During the last 20 years he had himself seen a great change in obstetrical interest in the life and freedom from injury of the child. Whereas formerly the baby received scant consideration, now, while the interests of the mother still had, and always would have, a prior claim, the life of the child was always taken into consideration of the best method of delivery.

He was, therefore, somewhat surprised to hear Dr. Findlay state that the percentage of birth injuries had been doubled. He thought this statement was not strictly true, and was probably due to the fact that the frequency of fatal intracranial hæmorrhages was not realised until a few years ago. Pædiatricians were responsible for the production of the healthy mothers of the next generation. The reduction of the maternal mortality depended largely on the prevention of contracted pelves, not only those due to rickets but also those, such as round pelves, due to postnatal developmental errors. So too the disappearance of infections, including rheumatism in juvenile life, would diminish the number of cardiac, renal, and arthritic maternal cripples.

REVIEWS AND NOTICES OF BOOKS

Fractures and their Complications.

By GEORGE EWART WILSON, M.B. Tor., F.R.C.S. Eng., F.A.C.S., Surgeon-in-Chief, St. Michael's Hospital, Toronto; Assistant Professor of Surgery, University of Toronto. London: Baillière, Tindall and Cox. 1931. Pp. 415. 35*s*.

THE routine use of radiography in the recognition and treatment of fractures has altered the clinician's attitude, and though it is still considered essential to impress upon students the signs by which to appreciate displacements characteristic of particular injuries, the surgeon is mostly concerned in diagnosis with X ray appearances. So it is with this author, whose book is thus adapted to the needs of the post-graduate rather than to those of the student. Nevertheless, the opening chapters, devoted to the morbid anatomy of fractures, their effects and processes of union, provide an attractive general exposition, and show the author to be a surgeon as well as the skilled mechanic that the later pages reveal. Frankly a personal work, the book describes Prof. Wilson's own methods with little reference to tradition or to the modern procedures of others, and it contains much which will stimulate controversy. The section devoted to cranial injuries properly emphasises the coexisting cerebral lesions, but the reference to the characters, prophylaxis, and management of the intracranial infections associated with fracture of the anterior fossa is so meagre as to mark an omission. In fractures of the limbs Prof. Wilson insists on the importance of fluoroscopic examination during reduction, an ideal not always to be reached in this country even in large hospitals. The treatment of the fractures of the upper limb is in accordance with the orthodox practice of the present day. The possibility of recurrence of deformity in Colles's fracture following premature relaxation of palmar flexion is duly noted, but we cannot agree that with fixation in flexion over-correction is impossible. The management of the femur here recommended is again orthodox, though no mention is made of the Thomas walking calliper during the early months of union. For the leg we should like to see some account of the ambulatory methods of Delbet, their indications and dangers, as an alternative to the prolonged plaster fixation recommended. The book is closely but well printed on clay paper and the illustrations are apposite, though the reproduction of the radiograms is not of uniform excellence.

Pye's Surgical Handicraft.

Tenth edition. By H. W. CARSON, F.R.C.S., late Senior Surgeon to the Prince of Wales General Hospital, Tottenham. Bristol: John Wright and Sons, Ltd. 1931. Pp. 641. 21*s*.

THIS latest edition of Pye was completely revised by Herbert Carson before his death and shows many signs of the thoroughness with which he always carried out his work. *As a guide* for house surgeons it remains unrivalled. Its usefulness is much enhanced by the collaboration of experts in certain of the specialties, though it seems unnecessary to procure a special description of the use of the Thomas splint, the great advantage of which is the simplicity of its underlying principles and application. We have tested the book from the house surgeon's point of view and find it likely to be helpful in almost any emergency and in most of those minor procedures which he is called upon to perform. In future editions help might be offered on the use of hypertonic magnesium sulphate in the treatment of head injuries, the dosage and details of administration of tetra-iodo-phenolphthalein, the preparation of the patient for sigmoidoscopy, the dosage of glycerin in an enema, the Dickson Wright treatment of varicose ulcer, the use of glucose saline and of insulin for shock, and the preparation of diabetics for operation. It is a great achievement for the editor to have freed himself from the trammels of tradition and arrangement and to have produced an edition which fulfills the requirements of the modern house surgeon as efficiently as did the original one when it was issued nearly 40 years ago.

Ultra-violet Radiotherapy.

By W. KERR RUSSELL, M.D., B.S., Medical Officer in Charge Light and Electrical Department, Miller General Hospital for South-East London. Modern Treatment Series. London: Jonathan Cape. 1931. Pp. 130. 5*s*.

IN a short note Dr. F. G. Crookshank, the general editor of the series to which this book belongs, states that the aim of these small volumes is to give practitioners an opportunity to obtain in convenient form and at small cost reliable guides to the present practice, and best opinion in some of the many branches of medicine and surgery. Considering the limitations of size imposed on him, and the difficulty of summarising a controversial subject, Dr. Kerr Russell has accomplished his task remarkably well. His exposition is lucid, dogmatic by necessity, but very accurate. The medical reader who is unfamiliar with the subject will not be puzzled by superfluous technical terms, and will not be irritated by the adoption of the "popular" style commonly associated with elementary manuals. More space could profitably have been allotted to physiological considerations and less to descriptions of apparatus. We question also whether a detailed description of the technique employed in treatments with the Finsen-Reyn lamp serves a useful purpose in a book of this scope. Anyone who might feel tempted to treat a case of lupus, for which this lamp is so frequently and successfully employed, after learning the very difficult technique in a book, will find that he has to learn all over again from his mistakes, a method not likely to benefit either the practitioner or the patient. Another omission in the introductory remarks is of some practical importance. Enumerating the type of cases which a biophysical assistant should not treat without direct medical supervision, Dr. Kerr Russell mentions pulmonary tuberculosis associated with hæmoptysis, but no other type of tuberculosis is specifically mentioned. All cases of tuberculosis, and more especially of phthisis, should be under direct medical supervision, and it is especially in the early or quiescent cases of pulmonary tuberculosis that irreparable damage can be done by injudicious light treatment. There are not many such omissions, and this small volume will be found informative and readable by both medical and lay workers.

Lectures on Diseases of Children.

Sixth edition. By Robert Hutchison, M.D., F.R.C.P., Physician to the London Hospital, and Hospital for Sick Children, Great Ormond-street. London: Edward Arnold and Co. 1931. Pp. 487. 21*s*.

A new edition of this work from which so large a number of students and doctors have obtained instruction and pleasure is always of interest, especially to those who have watched its evolution from a short series of well-chosen lectures to a volume which has achieved the completeness of a text-book and yet retained the characteristic style of the author's clinical teaching. In the sixth edition minor alterations have been made throughout the text; the lecture on the dyspepsias of childhood has been rewritten and a somewhat different classification adopted. Three new chapters have been added, dealing respectively with diet after the period of infancy, with asthma, and with chronic splenomegaly. The first of these adds greatly to the value of the book as a practical guide to routine work, and should act as a wholesome antidote to some of the faddy and pseudo-scientific suggestions with which the student is often beset. The lecture on splenomegaly provides a clear account of the difficulties of differential diagnosis in these conditions. This new edition will add to the influence which Dr. Hutchison's work exerts on the study of pædiatrics.

Clinical Nutrition and Feeding in Infancy and Childhood.

By I. Newton Kugelmass, M.D., Ph.D., Sc.D., Associate Attending Pediatrician, Fifth Avenue Hospital; Riverside Hospital; Director, Heckscher Institute for Child Health. London: J. B. Lippincott Company. 1930. Pp. 345. 25*s*.

The aim of this book is to interpret the science of nutrition for the benefit of the practitioner of medicine, or, as the author expresses it in the preface, "to temper scientific severity for clinical clarity." The result is that the practical problems of the feeding of infants and children in health and disease are presented as though no problems remained to be solved. Most of the paragraphs are preceded by a brief summary in heavy type of the argument that is to follow, and a selection of these headings will indicate the manner in which controversial subjects are treated. "Hypersensitiveness develops in utero as the result of the mother's over indulgence in certain protein foods." "Potential hæmorrhagic disease of the newborn may be prevented by prenatal feeding rich in protein and fat." "Acute intestinal intoxication in infancy is the result of an abnormal concentration of the blood." "Humanised dried milks are fool-proof feeding mixtures." It is true that much useful practical advice is contained in this volume, but it will scarcely appeal to those who believe that the science of nutrition has a future.

How You Work: An Introduction to the Human Body.

By Isabel Wilson, M.D. London: Gerald Howe, Ltd. 1930. Pp. 178. With 16 text-figures. 3*s*. 6*d*.

About 250 years ago Robert Boyle urged that it was "highly dishonourable for a reasonable soul to live in so divinely built a mansion as the body she resides in altogether unacquainted with the exquisite structure of it." If a child is a reasonable soul, we know of no introduction to the body and its working so well calculated to save him from a dishonourable ignorance. Whether young children—the wrapper mentions "8 years and upwards"—are quite reasonable enough is a question for pedagogues.

Clio Medica: Physiology.

By John F. Fulton, M.D., Sterling Professor of Physiology, Yale University. New York: Paul B. Hoeber. 1931. Pp. 141. $1.50.

Aristotle taught that animals live by virtue of their "innate heat." "The existence of life is coupled with the preservation of the heat aforesaid, and what is called death is the destruction thereof." It was some 2000 years later that Helmholtz proved that *muscular contraction is associated* with the evolution of heat, and by indicating the chemical transformations which produce this form of energy in the living tissues laid the foundations of biochemistry. It has been Prof. Fulton's task to indicate in broad outlines the main structure of physiological development in the space which separates these epochs. This he has done effectively; by tracing the history of knowledge with regard to the three great subjects of circulation, respiration, and digestion, and he has added a final chapter upon the rise of the modern laboratories and the trend of physiological research. He deprecates the tendency to pursue physiology too slavishly in the terms of the exact sciences and to lose sight of the great problems of integrated function in the fascinating and more exact bypaths of electrochemistry and biophysics. The production of a small readable handbook of this kind is a considerable achievement. The author has the gift of discretion and a sense of proportion. We have read the book with great pleasure and commend it to all those interested in the evolution of our knowledge of human function and, above all, to all students of medicine. We have detected only one inaccuracy. The author remarks that the Waynflete chair at Oxford, created in 1878, was the second chair of physiology to have been founded in Great Britain, Edinburgh having been the first. In this he is unfair to the University of Glasgow, which had, as early as 1832, a lectureship in the "Theory of Medicine" which was transformed into a chair of the "Institutes of Medicine" in 1839. The first occupant of the chair was Andrew Buchanan, who held it until 1876 when he retired under pressure, permitting himself in his valedictory address to explain to his students how a professor, who had no intention of retiring, might be got rid of *malgré lui*. Buchanan was succeeded in 1876 by McKendrick, when the title of the chair was changed to that of Physiology.

The price of "Physiological Chemistry," Fifth edition, by A. P. Mathews, published by Messrs. Baillière, Tindall and Cox, is 31*s*. 6*d*., not 15*s*. as stated last week.

THE LANCET.

LONDON: SATURDAY, MAY 2, 1931.

HOSPITALS AND PAY-BEDS.

THE plight of the voluntary hospitals is illustrated by the application last week to the Chancery Division for a scheme to increase the number of pay-beds in the Miller General Hospital for South-East London to 50. The board of management obtained the approval of the Charity Commissioners in January, 1929, to a scheme authorising the appropriation of not more than 15 pay-beds, for which a patient would be charged not more than £7 a week. The whole income of the hospital is derived from voluntary subscriptions, donations, and legacies, and from grants from King Edward's Hospital Fund. In 1929 the total income (including legacies) was under £35,000, as against expenditure of over £38,000. The deficiency of £3781 for 1929 has been estimated as likely to rise to £6394 for 1930. The board of management is able to make the point that the district of Greenwich and its environs has greatly changed its character, and now contains few inhabitants of more than small or moderate means; it is not anticipated that the annual subscriptions and donations can be kept up at the present level. In these circumstances the Charity Commissioners were asked to sanction an increase in the pay-beds, and the Commissioners referred the matter to the Court.

Counsel for the hospital said that either there must be more paying patients or else some of the wards must be closed; to close 74 beds would save £2071 in expenditure, but this would not solve their problem; the only solution, in the view of the board of management, was to establish more pay-beds. Counsel sought to support the change under what lawyers call the *cy-près* rule. This is a doctrine whereby the property of a charity is to be applied as nearly as possible to the donor's intentions; where the scope of the charitable purpose has ceased to exist—for instance, where charities exist for the release of captives imprisoned by the Barbary pirates—the doctrine enables the application of the charity to be varied. On behalf of the Attorney-General, who appears in these cases in order to represent the public interest, it was argued that the *cy-près* doctrine could be applied only if the proposed scheme was the sole possible method of obtaining financial relief. The Attorney-General was stated to be sympathetic to the financial difficulty, but unable to agree to a proposal which meant that one-third of the beds would become pay-beds, when under its rules the hospital existed to provide "free medical and surgical relief and assistance for necessitous poor." It was suggested that the hospital might get help in some other way, by applying to the Ministry of Health or to the London County Council under the Local Government Act, 1929. The Court adjourned the application for a fortnight to give an opportunity for the production of further evidence that all possible alternatives have been considered—though this fact would seem to have been already established. The Attorney-General seems to have hinted that he will favour an increase of pay-beds from 15 to 30—at any rate for an experimental period of 12 months—if it is proved, first, that there is no other way of obtaining relief; and, secondly, that without this relief a large part of the hospital must be closed or carried on in a very different way. The applicants had asked for the increase to 50 either during a limited period or otherwise.

Other hospitals, similarly placed, will watch the case with interest. Continuous increase in taxation dries up voluntary subscriptions, and there are disturbing influences at work for the future.

◆

MEDICAL PATENTS.

THE problems involved in patents of therapeutic substances are of relatively recent origin. It was not until the late war caused a lack of certain drugs, many of which were subject to patent rights in this country, that the question came before the attention of those concerned with patent rights. The result was Section 38A of the Patents and Designs Act, 1919, which enacted that the comptroller might grant a licence for the preparation of a food or medicine, and should settle the terms of the licence and the amount of the royalty with due consideration for making the food or medicine available to the public at the lowest possible cost, while allowing the inventor a proper reward for his research. This measure aroused considerable controversy in certain quarters, and still further publicity was given to the matter by the alleged commercial abuse of certain medical discoveries and the safeguarding by patent rights of insulin and other new preparations. A large section of the medical profession refused to sanction medical patents in any form, and the British chemical manufacturers declared that their work was being handicapped by this attitude, since it was not shared by many foreign workers. The question came before the representative body of the British Medical Association last year.[1] The attitude of the Association's ethical committee was that a registered medical practitioner ought not to derive any financial benefit from any medical invention or discovery, but that, on the other hand, medical practitioners could not desire to hinder industry or commercial research. A motion to affirm the old ethical position was referred back to the council on the ground that under modern conditions patents must be taken out, for the sake of the public as well as of the manufacturers. The council has once more considered the matter and recommends that the representative body shall this year express the opinion that medical men inventing or discovering substances or processes likely to be of therapeutic value may with propriety use the arrangements allowed by the law for protecting them. They may also accept a just reward, subject to the traditional ethical principle that they must not act against the public interests by unduly restricting the use or knowledge of inventions for their own gain.[2] How this suggestion will appeal to the representative body remains to be seen.

---

[1] THE LANCET, 1930, ii., 256.

Meanwhile the Board of Trade has published a report[3] on the subject. The departmental committee heard evidence from—among many others—a joint chemical committee representing several institutions and from the British Medical Association and the Medical Research Council. The joint chemical committee suggested a scheme by means of which dedication would be compulsory for all patents taken out for inventions subserving medical purposes. It was argued that this would assist publication, preserve the British worker from exploitation and prevent any uncontrolled monopoly. The proposal was supported by the representatives of the British Medical Association and the Medical Research Council, but was opposed by a number of other witnesses, chiefly on the ground that any further restrictions on medical patents would discourage research or encourage secrecy. The committee, after very careful consideration, came to the conclusion that dedicated patents would discriminate unfairly against research workers and the fine-chemicals industry in this country and that a sufficient case had not been made out for their adoption. The committee do, however, recommend an alteration in the section where it says: "In the case of inventions relating to substances prepared or produced by chemical processes or intended for food or medicine, the specification shall not include claims for the substance itself, except when prepared or produced by the special methods or processes of manufacture described and claimed or by their obvious chemical equivalents." A decision of the law officer on the word "special" in this section had led in some cases to the refusal of patents for inventions produced by processes which could not be said to contain features of substantial novelty. The word "special" has enabled the Patent Office to refuse applications for mere prescriptions but, as a result of their attempt to hold the balance between avoiding the encouragement of futile claims and not unduly hampering invention, the committee have decided to recommend the substitution of the word "particular" for the word "special," together with the addition of a proviso stating that a mere admixture resulting in an aggregation of the known properties of the respective ingredients shall not be deemed to be a particular process of manufacture.

MOTTLED TEETH.

THE enamel of the teeth, until destroyed by disease or old age, remains as an outward and visible sign of metabolic disturbances occurring in the first three or four years of life. While this statement can hardly be challenged, it does not mean that enamel, once formed, remains unaltered by nutritional changes, for the work of J. H. MUMMERY, E. SPRAWSON, E. W. FISH, and others has shown that enamel is a vital tissue capable of reacting to metabolic changes. But these changes affect the intimate structure of the enamel without changing its outward appearance, so that defects present when the teeth erupt are still apparent in adult life. This defective structure, conveniently termed hypoplasia, may be produced in various ways. A severe honeycombing of the enamel may be associated with rickets. A narrow zone of defective enamel forming a ridge or series of pits running transversely across the crown of an incisor may be caused by childish diseases such as measles or diphtheria. In animals, as MRS. MELLANBY has shown, an absence of vitamin D in the diet may bring about defective enamel formation, with the inference that a similar food deficiency may be responsible for dental hypoplasia in man. It is often possible by examining the teeth to state with fair accuracy the time and duration of some disturbance of metabolism which occurred many years previously. An interesting form of hypoplasia is one described by G. V. BLACK and F. S. MCKAY as mottled teeth. In this condition, while the teeth are of normal form, the cementing substance uniting the rods which form the bulk of the enamel is stained brown or yellow, less commonly opaque white. According to MCKAY, the staining does not occur until after eruption, but it is always preceded by the characteristic mottling. On chemical analysis the stain has been found to contain manganese.

The first account of mottled enamel was given by J. M. EAGER, of the United States Public Health Service, who noticed its frequency among Italian emigrants from Pozzuoli, near Naples. BLACK and MCKAY have since described its occurrence in Colorado, Texas, Virginia, Arizona, and other parts of America; it has been found to exist in regions as far removed from each other as the Bahama Islands, China, Holland, and South Africa. Wherever it occurs the appearance of the enamel is the same. BLACK and MCKAY came to the conclusion that the defect is due to some abnormal constituent of the water supply; but so far the exact nature of the causal agent and the way it acts remain unknown. The latest contribution[1] relates the occurrence of mottled enamel in Bauxite, Arkansas, a community established in 1901 to provide homes for a mining company. The original water supply was from shallow wells and a few springs, but as the population increased three deep wells were dug and the water piped into the homes; the shallow wells were filled in and the sole supply was from the deep wells, the water of which had a disagreeable alkaline taste. A careful examination of the school-children was carried out, and the results correlated with the known dates when the water supply was changed; it was found that no cases of mottled enamel antedated the introduction of deep well-water. The oldest individual with enamel defect was born about the time the deep wells were used. All those who had used the deep well-water during the period of tooth formation had mottled enamel; no child in the town who had lived elsewhere while the teeth were being calcified had this defect. Certain individuals resident in the town and attending school there, but living beyond the area of the distribution of deep well-water, had normal enamel. The strict dependence of the defect on some factor affecting the whole community is shown by the results of the examination of 14 people from 15 to 24 years who had lived in Bauxite two years or more during the period while the wisdom teeth were being formed. The teeth showed clearly that the incidence of mottled enamel depended on the periods when they had lived at Bauxite. In one person who came to the town at four years the incisors had escaped, for they began to calcify previously, but the remaining teeth, including the wisdom teeth, were affected. Another was born at Bauxite and lived there all his life; all the teeth were affected. Eight individuals came to Bauxite between 8 and 12 years, and only the wisdom teeth showed the enamel defect. To serve as a control the children of a neighbouring town were examined. None of them showed mottled enamel, except a certain number who had lived at Bauxite for varying periods during enamel formation.

[3] Report of the Departmental Committee on the Patents and Designs Acts and Practice of the Patent Office, 1931. H.M. Stationery Office. Pp. 104. 1s. 6d.

[1] G. A. Kempf and F. S. McKay. U.S. Public Health Reports. Nov. 28th, 1930.

The data gathered in this survey clearly indicate that there is a specific agent or condition in the environment of the town of Bauxite which affects the formation of the enamel of the permanent teeth. This agent is limited to the town, for children living outside escaped. It did not seem probable that food could be the factor, for the mode of life and the diet was the same in the town as in surrounding communities, and the population was attacked irrespective of social status. But while the evidence pointed strongly to the water supply as the incriminating agent, analyses of the water threw no light on the nature of the causative factor. An interesting sequel to this investigation was that steps were at once taken to abandon the deep well supply, and to substitute for it water brought from an adjacent town in which mottled enamel did not occur. This involved piping the water for four miles and passing it through a filtration plant. Bauxite is, we believe, the second community in the world to abandon an apparently satisfactory water supply solely because the evidence suggested that its use was responsible for defective structure of the teeth. A further survey of the community is promised at a later date to ascertain whether the change will bring about the disappearance of mottled teeth. But for this survey we must wait six or seven years.

ANNOTATIONS

IRRIGATION NEW AND OLD.

In a country like Bengal a right policy for irrigation implies not only cheap food and other necessaries but healthy surroundings for the agricultural millions. Sir William Willcocks in a series of lectures now reprinted[1] considers that a wrong policy has been adopted for the last 70 years, with results in certain areas which appalled the delegates of the League of Nations when they made a malaria tour of India some time ago. The history of irrigation systems is full of interest. Six thousand years ago the Egyptians introduced basin irrigation in the Nile valley, digging canals which remain in use to-day. At about the same period the Babylonian kings started perennial irrigation in the joint delta of the Euphrates and Tigris. Three thousand years later, in the light of the ancient knowledge, the Chola kings of Bengal evolved a system of overflow irrigation which led to an era of health and wealth such as central and eastern Bengal have never equalled since it was abandoned. If the views put forward in these lectures are justified—and there is evidently an increasing volume of informed opinion in their favour—the record of irrigation under British auspices in Bengal is deplorable.

Conditions in the Ganges delta are of course widely different from those in Egypt, which is practically rainless, and Babylonia, where there is little rain. A great part of Bengal enjoys an annual rainfall of 50-60 inches. This comes just when all the rivers are in flood, and it was to make full use of the rich waters of the Ganges and Damodar floods, in conjunction with the abundant but poor water of the monsoon rainfall, that the system of overflow irrigation was instituted. Unfortunately the canals were neglected and fell into disuse in the disturbed period which followed the Mahratha-Afghan wars of the eighteenth century. According to Willcocks these works were carried out on the soundest principles. The Damodar was closed and diverted, recalling similar feats performed by the ancient Egyptians when they diverted the Nile to protect the temples of Memphis, and by the Babylonians who turned the Tigris out of its course. In the Ganges and Damodar areas some seven to ten million acres of land were eventually irrigated. The canals still remain as "dead rivers," which have wandered somewhat from their original straight course, owing to the uncontrolled action of the waters, but would still serve their purpose. All they require is re-excavating. In the nineteenth century however the government adopted an irrigation policy which Willcocks holds to have been mistaken. Overflow irrigation on the ancient lines is, he thinks, the only method suitable in Bengal. The Irrigation Department has tried every other kind of project, and all have failed.

When Bernier visited Bengal about the year 1660 he considered it "richer than Egypt." There were immense herds of pigs and goats, and flocks of sheep; fish of every kind abounded; rice, sugar and butter, cotton and silks, were exported in large quantities. A magnificent system of canals served for both navigation and irrigation. Great tracts of country present a very different aspect to-day. The canals are silted up. Railway embankments and roads have obstructed the natural drainage, with the result that large areas have become waterlogged, or gone out of cultivation, and malaria, which was apparently not excessively prevalent in the ancient times, has become a national plague. The fish supply—formerly a very important factor in the diet of the people—has diminished, owing to the absence of the ova which used to be distributed broadcast by the muddy inundations, which also fertilised the soil. The fry which hatched out from these ova played an important part in keeping down mosquitoes, and there is good medical authority for the statement that the increase in malaria has been partly due to the elimination of this factor. Prof. C. A. Bentley is strongly of this opinion in his book "Malaria and Agriculture," while Dr. Bruce Mayne, in a malaria survey of Tanjore where the overflow system prevails, has come to the conclusion that irrigation of this kind stamps out malaria. The disease was only prevalent in the dry parts, in marked contrast to ordinary clear water irrigation where malaria follows the canals.

---

[1] Four Lectures on the Ancient System of Irrigation in Bengal and its Application to Modern Problems. By Sir William Willcocks. Calcutta: University Press. 1930. Pp. 128.

Sir William Willcocks's historic work in Egypt and Mesopotamia gives him a peculiar claim to speak on irrigation, and when he urges that the modern policy in Bengal needs reconsideration his views should command attention.

OCCUPATIONAL NYSTAGMUS.

It is often taken for granted that occupational nystagmus is confined to miners, but in the *Journal* of the American Medical Association for April 4th Dr. Carey P. McCord describes its extensive occurrence in train dispatchers, whose work involves following the continual motion of a large paper train sheet, whilst making rapid decisions upon which may depend life and death for passengers or crew. Among 121 subjects 67 per cent. showed nystagmus, 65 per cent. showed deviations from the normal mental state, of which anxiety neurosis was the most common, and 82 per cent. showed cardiovascular disorders. The combination of these signs and symptoms in individual cases was not recorded, but they have apparently the same erratic association as that found in workers in safety-lamp mines. Dr. McCord seems to have been influenced by English writings on miners' nystagmus, and three ætiological views can be extracted from his account: (*a*) the nystagmus may fit into a general fatigue syndrome characterised by nystagmus, intention tremors, tremors of other portions of the body, such as the eyelids, tachycardia or brachycardia, anxiety neurosis, and vasomotor disturbances; (*b*) anxiety neuroses are a natural product of the usual stress and strain incident to the responsibilities of train dispatching in safely moving trains; and (*c*) the high frequency of the use of eyes in connexion with train sheet work leads to overworking of the ocular mechanism, resulting in a nervous syndrome characterised by nystagmus, blepharospasm, some visual impairment, and ocular discomfort. Another association of nystagmus with neurosis, this time in workers on maritime cranes in the port of Genoa, was described by Tedeschi in 1908 in *Ramazzini* (an Italian public health journal now defunct). He emphasised the dangers and discomforts of the work and the need for constant watching of the hook on the end of the chain by which goods were hoisted, and described a resulting disorder that he called "fear neurosis." Some of the subjects of this disorder (29 per cent.) showed nystagmus, but Tedeschi regarded the neurosis as the important and primary condition. It is noteworthy that in each of these examples, as in miners, there is a curious association, not always in the same subjects, of the typical nervous results of danger and stress with oscillation of the eyeballs. In miners there is the additional fact that the majority of men who show oscillation suffer from no symptoms whatever. The orthodox belief that oscillation of the eyeballs causes the nervous symptoms in miners' nystagmus is challenged by psychopathologists, and these examples from America and Italy suggest that the application of statistical methods may support the view that psychoneurotic syndromes in miners do not possess a unique pathology but fall into line with what is known about the general ætiology of anxiety states. Whether the oscillation is a harmless manifestation whose association with the psychoneurosis is haphazard, or whether it is itself merely an accidental part of the psychoneurotic syndrome called forth by special circumstances of ocular stress, will remain an interesting if unimportant problem.

HÆMOSIDERINURIA.

A CASE of hæmosiderinuria has recently been described at length by Prof. Ettore Marchiafava, of Rome.[1] Hæmolytic anæmia with presistent hæmosiderinuria is a form of anæmia not yet classified, and consists in a chronic progressive fatal anæmia, without splenomegaly, and with intense hæmosiderosis of the kidneys alone.

The patient, an airman, was 32 years of age, and began to suffer in 1923 from anæmia with a red-cell count of 2,900,000 and white 7000. In 1927 his condition was thoroughly investigated; the red cells were then 3,078,000, the white cells 4000, and the hæmoglobin content 63. There was notable anisocytosis with microcytes and macrocytes; there was also some anisochromia but poikilocytosis was scanty. Spectroscopic examination of the blood-serum did not reveal the presence of hæmoglobin; van den Bergh's reaction was positive indirect, negative direct. The urine was, as a rule, clear, with short periods when it was wine red and turbid. Microscopic examination of the sediment of the clear urine showed renal cells containing granular matter and casts with infiltration of the same kind. This infiltration gave a blue colour with ferrocyanide of potassium, showing the presence of iron. There were no red cells in this sediment. At the periods in which the urine became coffee-coloured the sediment had the same characteristics as those of hæmoglobinuria with hæmoglobin casts, which, however, did not give the iron reaction. The condition of the patient continued to deteriorate, and in July, 1928, the red cells numbered 1,968,000, the white cells 3000, and there was marked anisocytosis, polynuclear leucopenia, and lymphocytosis. The number of red cells having fallen further to 1,600,000, splenectomy was performed. After two infusions the condition improved but the hæmosiderinuria persisted, and after a three months' interval febrile symptoms set in and ended in the patient's death. At the autopsy there was no trace of siderosis in the liver; the kidneys were large, and showed the presence of iron only in the convoluted tubes; the other organs were free from it, including the spleen.

The ætiology of the disease remains obscure. Of its hæmolytic nature, on the other hand, there is no doubt, as is shown by the continuous elimination through the kidneys of the colouring matter of the blood transformed into hæmosiderin, and by the recurrent hæmoglobinuria. This transformation into one of the hæmosiderinic group, giving an iron reaction, occurs through the operation of living cellular organisms—i.e., the epithelium of the secreting portions of the kidneys. That the spleen could have in this case an abormal destructive function, either within its own parenchyma, or in the circulating blood, as happens invariably in other forms of hæmolytic anæmia, is excluded not so much by the absence of any trace of hæmosiderosis in it as by the failure of any beneficial effect from its ablation. As to the seat of the hæmolysis, it is not the spleen—for the foregoing reasons—nor the liver, nor the bone-marrow, nor the lymphatic glands, since it is impossible to imagine that globular destruction could take place in these organs without leaving the necessary residual changes. Hæmolysis in the circulating blood is not reconcilable with the absence of splenic enlargement, of siderosis in the liver, or of copious urobilinuria, and with the fact observed by Micheli that the amount of iron, which is increased in the urine, remains normal in the fæces. The red cell destruction must therefore take place in the vascular system of the kidneys, and occurs in two ways, one persistent and slow by the transformation of the hæmoglobin into hæmosiderin in the protoplasm of the renal epithelium, the other rapid and violent, whence the recurrent hæmoglobinuric crises. The disease, of which the case described is an example, is a form of anæmia of a special type which is easily distinguishable from all other forms—i.e., hæmolytic splenomegaly, pernicious anæmia, and the various forms of hæmoglobinuria. Micheli proposes to give to this disease the name of "hæmolytic anæmia with hæmoglobinuria and hæmosidinuria." But considering that the hæmoglobinuria shows itself only by crises at variable intervals and sometimes as in the first case described by Nazari once only in the long course of the disease, and considering that on the contrary the hæmosiderinuria is constant and persistent up to the day of death, it appears that the greater importance is attached to this, and that the proper appellation should be hæmolytic anæmia with persistent hæmosiderinuria.

FACTORS IN SEXUAL IMPOTENCE.

THE sexual neurotic is unhappy not only because of his disability but because he is generally in despair of finding anyone who is prepared or able to help him. As Mr. Townley Clarkson pointed out last Friday at a meeting of the Society for the Study of Venereal Disease, impotence lies in the no-man's land of ailments between the neighbouring claims of the genito-urinary surgeon and the neurologist. The surgeon, as a rule, has little time for what he too frequently regards as a minor ailment, whilst the neurologist, skilled though he be in the treatment of functional disorders, has little expert knowledge of the organic lesions that may attack the organs of sex. Mr. Kenneth Walker, in his opening paper at the same meeting, laid stress on the psychological factors in the causation of impotence. Even when an organic lesion is found it is more likely than not that this has served only as a nucleus around which a functional trouble has formed. This indeed is the manner in which many other functional disorders arise, and although the elimination of the original lesion may be part of the treatment, a cure will not be effected unless the psychological difficulties to which the lesion has given rise are got rid of. It was, he pointed out, a matter of considerable difficulty to interpret the exact significance of the changes which were found in the genital tract of sufferers from primary impotence. These changes were well recognised by genito-urinary surgeons, and consisted of a swelling and tenderness of the prostate, and particularly of that portion of it known to anatomists as the verumontanum. Sometimes, when the trouble had been preceded by a prostatitis, these changes were definitely the cause of the impotence, but more often than not no history of infection could be obtained, and the changes in his opinion must be considered secondary rather than primary. Functional disorders were often associated with an upset in vaso-motor control, and the swollen and hyperæsthetic verumontanum of impotence was a phenomenon similar in nature to the *tache cérébrale* of hysteria. But while laying emphasis on the psychological factors in the causation of primary impotence, the physical investigation of the genitalia was, in Mr. Walker's opinion, of the very greatest importance, not only because of the necessity of discovering any organic lesion that might be present, but because it was only by being thorough that the patient's confidence could be gained.

THE NEGATIVE PHASE IN ANTIDIPHTHERIAL IMMUNISATION.

Dr. Richard Prigge[1] has been carrying out investigations in the State Institute for Experimental Therapeutics at Frankfurt a.M. to determine whether active immunisation of guinea-pigs against diphtheria produces a so-called "negative phase" or increased susceptibility to the disease. He found that guinea-pigs which had been immunised against diphtheria toxin or living diphtheria bacilli did not show any increased susceptibility to diphtheria toxin before immunity was obtained, nor any increased susceptibility to infection by diphtheria bacilli provided that the doses of the vaccine were not too high. Increased susceptibility was only produced when a large overdose of the vaccine had been used. He was unable to decide whether a negative phase in the ordinary sense of the term had taken place in this experimental intentional overdosage which is not likely to occur in the human subject, or whether the symptoms were merely the result of an excessively large dose of vaccine. In human inoculation of diphtheria toxin the dose employed is 1 to 200 times smaller than that used in experiments on animals without causing an increase in susceptibility. The experiments strongly suggest that the development of increased susceptibility, or of the so-called negative phase, can be excluded in human inoculation against diphtheria.

TESTICULAR GRAFTS ON RAMS.

THE somewhat extravagant claims made by grafting enthusiasts have induced two Australian veterinary surgeons, Mr. R. M. C. Gunn and Mr. H. R. Seddon, to repeat the experiments carried out by Voronoff and record their results.[2] The rams used were divided into three groups. In the first group the object was to determine the fact of testicular tissue being viable after being grafted for varying periods into the scrotum of young male rams. The second group was employed to determine whether increased production and hastened maturity could be obtained by means of the testicular grafts, and the third to determine whether old senile sterile rams could be reinvigorated and rejuvenated. The operative technique employed was that which Voronoff has made familiar. The conclusions arrived at were as follows: (1) Normal living, but not growing, testicular and epididymal tissue can be recovered as long as 24 days after grafting merino rams. (2) Absorption of testicular tissue grafted on the parietal tunica vaginalis of the scrotum appears to be rapid, usually occurring in young rams within one year. (3) There is no good evidence of any beneficial influence on body-weight or wool-production as a result of testicular grafting or of injections of pulped testis or saline extract of testis. The operations were done with a proper use of control animals and in a critical attitude of mind. Whilst the results seem to establish Voronoff's contention that grafts implanted by the method he recommends are viable, they clearly indicate that they do not live so long as he supposed. Gunn and Seddon point out that any beneficial effect produced by the absorption of grafts can be of very little importance since the storage capacity of testicular tissue is infinitesimal. Apparently, therefore, testicular grafting is not likely to be of much use either in human or in veterinary practice. In any case its high cost would limit its utility in the stock-breeding yard.

TRACHOMA IN POLAND

AMONG the general population of Poland the incidence of trachoma is estimated at about 1 to 1·5 per cent. It had a great stimulus after the war when about 3,000,000 refugees were repatriated from Russia. In 1919 compulsory notification was enacted and the numbers notified rose continuously between 1920 and 1929. The measures taken to combat the scourge are told by Dr. M. Zachert, chief of the anti-trachoma service.[1] Special dispensaries, hospitals, and mobile units have been founded and the number of cases treated in 1929 at these institutions was over 35,000. Periodical examinations are made in the schools and among recruits, children's refuges, and orphanages. Thirteen special hospitals for trachomatous children have been founded, each hospital having a school so that the children's education can be carried on uninterruptedly just as it is at Swanley. The results obtained in these hospitals have been distinctly good. Out of 6640 children admitted in ten years 5157 have been cured. Whereas in 1924 the percentage of trachomatous children in the orphanages was 13 per cent., in 1929 it was reduced to 5 per cent. We are not told in what the routine treatment producing this result consisted. Besides the hospitals for children there were in 1929 260 dispensaries treating over 31,000 trachomatous patients and two mobile hospitals in which operations were performed. An important part of the campaign is the holding of special trachoma classes for doctors at the State School of Hygiene, the number of doctors having attended these courses being 220. The whole campaign is financed by the State, the amount allocated to it in the budget of 1929 being a million and a half French francs.

PLANKTON AND BACTERIA IN SEWAGE.

THE rôle of bacteria in the purification of sewage has been recognised for the last 40 years, and it is well known that the bacterial flora of an effluent is, under *suitable conditions, an efficient oxidising agent.* The less numerous but nevertheless large population of infusoria or protozoa always found in sewage and polluted waters has been less carefully studied, although the presence of such organisms has been recognised as collateral evidence of pollution. In the sea the drift of this vast population of feebly motile organisms, conveniently known as plankton, determines the movements of the fish which feed on it, for the plankton is to the sea what the grass is to the land. The United States Public Health Service has been conducting researches on the more intimate mechanism of sewage pollution, and in a recent report[1] C. T. Butterfield, W. C. Purdy, and E. J. Theriault have described the influence of typical plankton on the biochemical oxidation of organic matter. Having prepared dilute dextrose-peptone solutions which could be readily and accurately reproduced, and which could be kept, when sterile, for long periods without absorbing the oxygen of the air dissolved in them, they studied the effect of inoculation with various bacteria. These in all cases multiplied rapidly and absorbed oxygen until in about two days a limit of both bacterial population and oxygen absorption was reached, this state being sooner and more definite with pure culture than with mixed organisms. A technique having been devised whereby colpidium, a small paramecium-like organism, could be washed and kept free from bacteria, cultures of this were introduced into the dilute (5 mg. per litre) and sterile dextrose-peptone medium in which they did not multiply, although they throve fairly well in a *medium a hundred times the strength,* showing that a certain concentration of food was necessary if they were to be kept alive on a slop diet. When introduced into solutions seeded with bacteria the result was very different. The bacteria increased as before, but as the protozoa also increased their numbers fell off to a fairly steady figure and both kinds of organisms lived together, oxygen absorption going on steadily as it does in naturally polluted water. It seems therefore that in this, as in similar cases among the higher animals, a balance of vegetable and animal life, of food collectors and food consumers, is reached. The only stable communities are complex ones, the predatory members of which, by taking their toll of the others, enable them in the mass to live successfully and to fulfil their natural functions, which in this case, from an economic standpoint, is the collection of putrescent colloid and other matter for oxidation. Protozoa, it would therefore seem, are useful members of biological filters, and their presence is vitally necessary in activated sludge.

THE GROWTH OF VISUAL PERCEPTION IN CHILDREN.

IT has been frequently suggested both by physiologists and psychologists that perception is subject to laws of its own; that, in fact, these are very elementary compared with the appreciations of the external world in which fully fledged intelligence is in operation. The work of the Spearman school, which has given *an impulse and new direction* to the mathematical assessment of general intelligence (or rather the function "g"), has led to the exploration of the whole process of cognition by means of graduated test material. With this guiding principle of method in the forefront of the investigator's mind, the special abilities in man were investigated separately and correlated with such particular functions as imagination, and with the processes involved in practice, fatigue, and perseveration. It is inherent in the Spearman theory that perceptual experience which falls within the laws of cognition should also be obedient to the same laws of the mind, as the higher processes of cognition—that is, the eduction of relations and the eduction of correlates.

Prof. W. Line,[2] working in the school of Spearman, has come to the conclusion, from carefully calibrated tests, that it is futile to use separate tests for perceptual experience and that dichotomy of thought and perception is not acute, but one of degree only, and that quantitatively and qualitatively the same laws of cognition are in operation. It is necessary, in the interest of clarity, to pause and consider what this discovery means, for it brings into the discussion the much debated theory of perception for which we are indebted to Kohler, Koffka, and Wertheimer, the so-called Gestalt or configuration theory of perception, and its relation to the apparently divergent theory of relational perception which is the outcome of the Spearman school to which Line enthusiastically belongs. In fact, Line has, from his carefully planned research, shown what he believes to be the truth of Spearman's laws of cognition as applied to visual perception. He stresses the distinction, however, between primary and secondary perception. The first includes the bare apprehension of a percept and the eduction of relations, while the second embraces supplementation due to past experience, together with supplementation which is due to the eduction of correlates. In his researches he discovers that "the growth in the capacity to perceive similarities of 'form' appears to take place in a manner directly parallel to the development of 'g,' at least, the two powers are highly correlated." His results point to what he calls a multistratal growth—an increase in the capacity to perceive relations in all levels simultaneously. In arranging his investigation he chose for his test material spacial diagrams, with and without meaning, pictures with meaning, three-dimensional models, and cinematographic representations. He draws the conclusion that in the appeciation of relations we have "the very woof and warp of shapes or whole qualities. The elementary relations of the lowest levels in themselves form fundaments for relations of the highest order."

[1] U.S. Treasury Dept. Public Health Reports, 1931, xlvi., 393–426.

[2] Monograph Supplement XV., Brit. Jour. of Psychol., 1931, 12*s*. 6*d*.

Prof. Spearman believes that Prof. Line has given a new orientation to the subject of mental testing, and believes that the light that this investigation throws upon perceptual growth must lead to the discarding of many established tests. The fact remains, however, that the fundamental concept of relations belongs to epistimological studies rather than to the domain of experimental psychology—that is, do relations as such exist in the mind independent of the terms which they bind together? The speculation, however, does nothing to detract from Prof. Line's thorough and stimulating inquiry.

THE PATHOGENESIS OF PINK DISEASE.

In spite of the interest which pink disease has attracted since the publication of Swift in 1914, and of Feer in the early post-war years, the real nature of this disorder remains undecided. Though much work has been done on the morbid anatomy, the findings of different observers have varied so much that no single lesion has been established as essential. The morbid changes in peripheral nerves and anterior horn cells found in some cases have been absent in others, and their underlying cause is still obscure. Hypotheses to account for the condition have been based on clinical analogies rather than positive evidence. Of these hypotheses, one which was in some favour a few years ago, especially in America, arose from the resemblance borne by pink disease to pellagra, from which it was inferred that it was a manifestation of avitaminosis. Latterly this view has somewhat lost ground, because of the number of cases reported in which vitamin deficiency could be excluded. There remain as alternatives those old favourites, the alimentary toxæmia, absorption from septic foci, and systemic infection, and for none of these has the case yet been proved.

The view that pink disease is infective is strongly supported by M. Péhu and A. Mestrallet.[1] They have previously sought to establish its nosological identity with the epidemic "acrodynia" of 1828 and they now bring forward further arguments in favour of its being a specific infection of the nervous system closely analogous to encephalitis. The cases, they say, show signs of grouping into certain localities, and some of the psychic disturbances, notably the intractable insomnia, bear out the analogy. From the standpoint of morbid histology further arguments are adduced. They give a full summary of two published necropsies (Francioni and Vigi, Kernohan and Kennedy) and compare them with the findings of Paterson and Greenfield, Byfield, and others. In the first case the most significant observations were degenerative changes in the cells of certain mesencephalic ganglia; Francioni and Vigi also found cellular infiltration in the region of the cervical sympathetic ganglia, of the nature of perivascular cuffing. The changes found by Kernohan and Kennedy were more diffuse; there were signs of degeneration and demyelination (but not inflammation) in some peripheral nerves, especially the sciatic, and some chromatolysis in the posterior root ganglia; chromatolysis was seen to the greatest extent in the cells of the mesencephalic ganglia. A point on which all the observers quoted are in agreement is that the cells of the hemispheres and cerebellum are unaffected, though Warthin found a condition of meningeal œdema.

Péhu and Mestrallet think the evidence they have collected justifies the classification of acrodynia as an infective disease closely allied to encephalitis, probably caused by a neurotropic virus which produces diffuse lesions but shows a predilection for the mesencephalic centres of the autonomic system.

STREPTOCOCCAL VARIATION.

It was Prof. H. Schottmüller, of Hamburg, who first classified the streptococci according to their action on red blood corpuscles incorporated in the culture media on which they are grown. As is well known some of the streptococcal colonies show after incubation a clear area around them in which the red cells are completely hæmolysed, others show a green appearance due to partial hæmolysis, and yet a third group appears to have no action on the red corpuscles in the culture material—the groups being named respectively as hæmolytic, green (*viridans*), and non-hæmolytic. How closely this grouping bears on the ability of the organism to produce disease in man is apparent from much recent work—witness the Guy's Hospital study on which we commented three weeks ago.[2] Schottmüller and his pupils have, however, now brought forward evidence[3] to show that while truly hæmolytic and green streptococci keep their characteristic appearances on subculture, a degradation of the hæmolytic streptococci into the appearance of *S. viridans* may under certain conditions occur. Their results appeared in the course of experiments on the relation of the infecting hæmolytic streptococci to puerperal fever. Normally the uninjured female vagina does not contain hæmolytic streptococci; these are introduced from without, as Semmelweis rightly surmised, and with the subsidence of the infection they disappear. Schottmüller and his fellow-workers have followed up this disappearance. They introduced hæmolytic streptococci, which had been incorporated in silk threads by placing the threads in virulent broth cultures and then drying them, into the vagina of healthy non-pregnant women and found that, on withdrawal after a few days and subculture, relatively few hæmolytic colonies were recovered but a correspondingly large number of green streptococci. Further a degradation of the hæmolytic streptococci occurred when the silk threads after drying between blotting-paper were left in sterile flasks; cultures made at varying times later showed that a dying-out of streptococci was accompanied by a diminution of the hæmolytic power of the remainder, and indeed by a loss of virulence to mice. The hæmolytic power and virulence could be rehabilitated when the streptococci were subcultured in fresh blood media or by passage through the bodies of laboratory animals such as mice. These results explain certain anomalies in the subculture of the hæmolytic group which have troubled bacteriologists. But there is no evidence that the true *S. viridans* can be made to take on hæmolytic powers. Its characters and pathogenicity bring it into a class by itself.

RADIOGRAPHY OF ABDOMINAL ARTERIES.

The use of arteriography in cerebral conditions was briefly reviewed in our issue of Jan. 31st. (p. 249). A similar method of examining the abdominal aorta and its branches is now described and illustrated by Portuguese workers [1] and has been applied, it is stated, in more than 100 cases. The aorta is punctured posteriorly, an opaque fluid is rapidly introduced through the needle, and a radiogram is taken during the injection. To limit and concentrate the circulation of the fluid in the branches of the aorta, tourniquets are applied to the upper thighs. The solution originally used was one of sodium iodide in high concentration, but this caused somewhat severe pain when it reached the smaller arteries and arterioles. The substance called abrodil, which is now employed instead, is an organic compound of iodine which is commonly used in urography. Twenty grammes are injected and it is said to prove relatively non-toxic, giving a good opaque shadow, and causing less pain than sodium iodide. It would be interesting to know whether the new Japanese substance named l'ombre would be even more satisfactory. As a preliminary the splanchnic nerves are anæsthetised by injection of novocain around the area in front of the twelfth dorsal and first lumbar vertebræ. The needle is inserted to a depth of 10 to 11 cm. from a point four fingers-breadth to the left of the mid-line posteriorly under the twelfth rib towards the vertebral bodies. After a short pause it is pushed in a further 1–2 cm. and pierces the abdominal aorta. The abrodil solution is then quickly injected by a special apparatus under a standard pressure and the films are taken at this moment. Stereoscopic photographs can be made and in this way the interpretation is made easier. In this technique the authors claim to have evolved a simple, certain, and harmless method of great value in diagnosis, because it shows the blood-vessels of the abdominal viscera. Since the abrodil is excreted by the kidneys it is, moreover, possible to secure radiograms of the urinary tract during the 10 or 20 minutes following the injection. The photographs reproduced certainly give a clear picture of the abdominal blood-vessels, and the method is likely to give important information about the anatomy and perhaps the physiology of the abdomen. Its value in the diagnosis of disease also seems to be considerable, though at present the technique is hardly perfect enough to warrant its general use. Its originators are to be congratulated, however, on their ingenuity and achievement.

---

[1] Santos, R. dos, Lamas, C., and Caldas, P.: Presse Méd., April 18th, p. 574.

We regret to announce the death on April 27th of Sir Byrom Bramwell, consulting physician to Edinburgh Royal Infirmary and sometime President of the Royal College of Physicians of Edinburgh. He was in his eighty-fourth year.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

The following appts. are made:—Surg. Comr. F. G. Hitch to *Victory*, for Haslar Hospital; Surg. Lt.-Comr. E. J. K. Weeks to *President*, for post-graduate course, and to *Tamar*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. M. B. H. Ritchie retires on retd. pay.

Maj. (temp. Lt.-Col.) D. F. Mackenzie to be Lt.-Col., vice Lt.-Col. M. B. H. Ritchie.

Maj. and Bt. Lt.-Col. T. H. Scott to be temp. Lt.-Col.

Lt. W. F. Lane to be Capt.

ARMY DENTAL CORPS.

C. A. Pank to be Lt. (on prob.).

ARMY RESERVE OF OFFICERS.

Maj. J. E. H. Gatt having attained the age limit of liability to recall ceases to belong to the Res. of Offrs.

TERRITORIAL ARMY.

Capt. C. S. Atkin resigns his commn. and retains his rank, with permission to wear the prescribed uniform.

Capt. W. S. C. Copeman, from Active List, to be Capt.

J. S. Moore (late Surg. Sub.-Lt. R.N.V.R.) and D. Macleod to be Lts.

G. K. Thornton (late Lt., R.F.A. Spec. Res.) to be Lt.

H. R. Ferguson (late Offr. Cadet, Cambridge Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

Supernumerary for Service with the O.T.C.—Lt. W. A. Mackey to be Capt.

ROYAL AIR FORCE.

Dental Branch.—Flying Officer A. P. Atkins is granted a non-permanent commission as a Flight Lieutenant.

Flight Lt. W. Wormington, Capt. A.D.C., relinquishes his temporary commission on return to Army duty.

Royal Medical Benevolent Fund.—During the first quarter of this year the sum of £3050 has been voted in grants to applicants, as against £2562 during the corresponding period of last year. Subscriptions received during the same period amounted in 1931 to £2499, but in 1930 to £2628. At the April meeting the committee voted £705 to 45 applicants.

One recipient was a widow aged 43 with a daughter aged 9 who called at the office of the Fund. Her husband qualified in 1914, joined the R.A.M.C. and served throughout the war. He was wounded at Ypres in 1915 and was four times mentioned in despatches. The latter part of his service was with the British Military Mission in Siberia. While there he married a Russian lady who was engaged in Red Cross work in Siberian Hospitals. After demobilisation he practised in the Far East from 1919 to 1930. As the result of an accident he died at the age of 42. The practice was sold, and it is expected that the estate will yield an income of £70 a year. The first dividend not being payable till June, the Fund has given a grant of £26 to the widow and arranged with another charity to give a similar sum to tide her over her present difficulty. The Royal Masonic Institution has undertaken the education of the child. Employment is urgently needed for the widow. She speaks English and French fluently as well as Russian.

Subscriptions and donations to the Fund should be addressed to the hon. treasurer at 11, Chandos-street, London, W. 1.

SPECIAL ARTICLES

IMMUNITY IN VIRUS DISEASES.*

By C. H. Andrewes, M.D., M.R.C.P. Lond.,
MEMBER OF THE SCIENTIFIC STAFF, NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMPSTEAD.

I.

Two properties of viruses are probably particularly mportant. Firstly, on their small size depend the facts that they will mostly pass through candles or membranes impermeable to the majority of bacteria and that they can be seen or stained not at all or only with great difficulty and by the aid of special methods. Secondly, they are apparently intracellular parasites, and this is probably the reason why so little success has been encountered in attempts to cultivate them on cell-free media; upon this property, too, doubtless depends the existence in many virus diseases of the remarkable intranuclear or cytoplasmic "inclusion bodies" which I shall refer to later. The immunological properties of viruses are probably related to both the above properties—small size and intracellular parasitism.

Duration of the Immunity.

The study of immunity to viruses is rather a hopeful one because in the field of active immunisation against viruses there are some striking successes which greatly encourage workers at the present day. Such successes probably depend largely on the fact that so many virus diseases leave behind them a solid and lasting immunity. If you go through the list of known virus diseases carefully, you cannot, I think, help being struck by the large numbers of virus diseases which *are* followed by solid immunity. A few are invariably fatal and therefore cannot be considered in this connexion. Of the rest you will find four familiar ones—herpes simplex, the common cold, influenza (if you believe that to be a virus disease), and foot-and-mouth disease, in which the mmunity is rather transient. But you will readily find a couple of dozen virus diseases in which the mmunity is fairly durable; these include most of the specific fevers of childhood (see Table I.). Indeed, the specific fevers are classed together partly because they are diseases of childhood which do not tend to recur. Adults infrequently get chicken-pox or poliomyelitis probably because they have had either the disease or a "subclinical infection"; adults in isolated communities such as the Faeroe Islands who have never been exposed to measles prove just as susceptible as children when they do come into contact with the infection.

Table I.—*Virus Diseases followed by—*

LASTING IMMUNITY.		TRANSIENT IMMUNITY.
Small-pox.	Poliomyelitis.	Common cold.
Measles.	Yellow fever.	Herpes simplex.
Mumps.	Cattle plague.	Foot-and-mouth disease.
Chicken-pox.	Swine fever.	Influenza (?)
Herpes zoster.	Dog distemper.	
&c. &c.	&c.	

The bacterial diseases whose symptoms are definitely associated with a toxin—e.g., diphtheria—leave behind a good immunity, but if I were to ask you to name others which do so you would say at once "typhoid fever," and then scratch your head and begin to think.

It is obviously nonsense to say that this question of solid or transient immunity will avail to demarcate virus diseases from bacterial ones; it is equally absurd to deny that viruses (and, we may add, toxins) have a stronger tendency than bacteria towards the production of a lasting immunity. Let us consider to what this lasting immunity can be due; three possible factors must be dealt with.

(1) CONSTANT REINFORCEMENT OF IMMUNITY.

Firstly, it is probable that immunity to any organism will last much longer if the immune person is constantly exposed to the infecting agent, so that the immunity following an attack of the disease is constantly being reinforced by little doses, too small to overwhelm his defences and give him a fresh attack. There is evidence that this is so as regards maintaining immunity to diphtheria and typhoid fever. It is very likely true with virus diseases also. With a virus like that of the common cold which leaves behind only a transient immunity such a mechanism probably plays a part. Witness the colds which immediately affect Arctic explorers as soon as they return to civilisation. But it does not follow that this reinforcement of immunity is essential in virus diseases. People who have had yellow fever in the tropics many years ago and have then gone to live in countries where the disease does not exist may be found, years and years afterwards, to have good neutralising antibodies in their serum.

(2) PERSISTENCE OF VIRUS IN IMMUNE HOST.

Secondly, it has been suggested that immunity to a virus may be associated with persistence of that virus in the immune animal; the same sort of thing is known to occur, of course, in syphilis. If viruses do so, it is presumably in some remote hiding place in the body, for convalescents from specific fevers due to viruses are not commonly a source of infection to others. It is possible, however, for vaccinia to persist in an inoculated rabbit for many weeks in spite of the presence of potent antibodies in the animal's body fluids, and for fowl-pox virus to remain even longer in the tissues of a recovered bird. An instructive example is afforded by the submaxillary virus of guinea-pigs. This virus occurs in the salivary glands of almost all adult guinea-pigs of certain stocks. Such adult guinea-pigs are immune to the effects of this virus introduced elsewhere into their bodies. But very young guinea-pigs, which do not harbour the virus in their salivary glands, will die of acute meningitis if the virus is inoculated into them intracerebrally, or they will develop an acute local lesion if it is injected into them at any other site. How the virus manages to persist at one site—in the salivary glands—of the immune adult guinea-pigs is a mystery.

A still more striking example is afforded by the infectious anæmia of horses. Here the blood of horses which have apparently recovered from the disease is found to be virulent when injected into other horses—for as long sometimes as 14 years afterwards. The horses carrying the virus thus are not, however, really immune as they may have a relapse at any time.

The idea that a virus may be latent in an immune or insusceptible host is a familiar one to workers with viruses infecting plants. Certain races of potato are immune from the attack of a certain kind of potato-mosaic virus, but when grafting experiments are carried out from such an immune race to a susceptible variety of potato, the susceptible race becomes infected and it thus becomes clear that the immune sort is a carrier of the virus, which must live in its tissues without causing any harm. I do not propose to discuss whether or not bacteriophage is a virus, but it certainly behaves like one in many respects; here again it appears that an organism like *B. coli* may permanently "carry" a phage which does not affect it, but can cause lysis of another organism, the dysentery bacillus. I am not suggesting that there is any certainty that this sort of thing is a usual occurrence with animal viruses; but the possibility is very well worth while bearing in mind.

---

* Two lectures (abridged), delivered at University College Hospital Medical School on March 17th and 24th, 1931.

(3) NATURE OF THE HUMORAL IMMUNITY.

The third factor which may help to explain the persistent immunity to viruses lies in the nature of the humoral immunity. In suggesting that this is somewhat different from humoral immunity to bacteria, I do not mean to imply that the body's response is necessarily different in the two cases; only that the antibody which develops may be effective in a rather different way. Bacteria sensitised or coated by antibody are not, by that alone, killed or prevented from multiplying; only when phagocytes come to engulf or destroy them or complement to lyse them are they put out of action. But it seems likely that a small body such as a virus when it unites with antibody may have its physical properties so altered that it cannot attack and enter the susceptible cell; the antibody has effectively neutralised it as an antitoxin does a toxin, directly, without the necessity of calling in complement or leucocytes to help it. This mode of neutralisation may well be more effective than the more cumbrous mechanism which has to be used against bacteria. As a rough generalisation it seems true that a purely humoral mechanism is most effective against the smallest noxious agents. It is very effective against toxins and viruses; less so against bacteria; still less so against larger things such as protozoa and worms.

It is possible passively to immunise animals against many virus-diseases with immune sera. These sera may be quite ridiculously effective; apparently one-tenth of 1 c.cm. of immune serum will suffice to confer upon a monkey a passive immunity which will protect it from infection with yellow fever virus. Extremely small quantities of serum will also passively protect against measles and dog distemper.

A number of experiments reveal that the inactivation of a virus by immune serum is not a perfectly simple business. One cannot simply say that the antibody unites with the virus and destroys it. On the contrary, one can inactivate a virus with immune serum and then restore its activity again. One can make a mixture of vaccinia virus with immune serum and have so much immune serum present that the mixture inoculated into a rabbit's skin in a dose of one-tenth of 1 c.cm. produces no lesion; one then dilutes the mixture ten or a hundred times and inoculates one-tenth of 1 c.cm. of that into the rabbit; though the rabbit receives only one-hundredth of the original dose of virus a lesion will commonly result; dilution has reactivated the neutral mixture. This phenomenon can be demonstrated with a number of viruses including fowl-plague, vaccinia, herpes, and poliomyelitis. This experiment along with others at one time led me to doubt whether virus and antibody united at all in the test-tube and to wonder whether the union might perhaps only occur in the body. This suggestion, however, is not a valid one; for if virus and serum are kept in contact for a long time in vitro it will no longer be possible to reactivate the mixture by dilution; a firm irreversible union has apparently occurred. This only takes place after some days in the case of vaccinia; with other viruses the firm union probably occurs after a few hours. This reactivation of a neutral mixture by dilution has a close parallel in experiments with toxins and antitoxins; neutral mixtures of tetanus, diphtheria, and botulinus toxins with their appropriate antisera can be rendered toxic again by dilution; but here again it is only possible when the mixtures have not been left standing for too long beforehand. It is supposed in this instance that the toxin-antitoxin union is at first loose and can be dissociated by dilution, but becomes firm and irreversible later; and it is extremely probable, though not yet proved, that the same is true of a virus-antibody combination. If it turns out that an immediate loose union of virus and antibody occurs, it is important to realise that this loose binding is most often quite effective in stopping the action of the virus; the later irreversible reaction (if you like, the actual killing of the virus) is an added luxury. For experiments which I shall refer to later make it clear that a virus can [illegible] a susceptible cell very rapidly (within a few minutes) and that immune serum can exert its protective action immediately—long before the virus-antibody union could have gone on to the irreversible stage.

Part Played by Complement and Leucocytes.

I stated that the immune sera could apparently neutralise a virus without the help of complement or leucocytes. It is difficult to be absolutely certain of this because one's ordinary test for neutralisation is to inoculate a serum-virus mixture into an animal, and although that mixture may contain no complement or leucocytes, yet these may, of course, be supplied as soon as the mixture gets inside the animal. Nevertheless, a good deal of indirect evidence suggests that they are not necessary. One can study the neutralisation by immune serum in tissue cultures. In vivo the virus of herpes simplex produces in cells of the rabbit's testis, both in cells of the parenchyma and interstitial tissues, oxyphilic intranuclear inclusion bodies. One can cultivate herpes in tissue cultures of rabbit testis in dilute rabbit serum. A very primitive technique will serve—one in which the tissue cells do not multiply, but merely survive for a few days. In such cultures there develop in the nuclei of the cells inclusion bodies exactly like those which the herpes virus forms in the living animal; one can look for these inclusions in stained sections of pieces of tissue from the cultures and thus tell whether or not the virus has grown, without recourse to any further animal experiment. Immune serum will protect the cells in such a culture so that no inclusions will develop and the virus will die out. One can be quite sure that leucocytes play no part in the inactivation of virus in such an experiment; the leucocytes present are scanty and immobile. One can be reasonably sure also that complement plays no part; for one can use washed cells, inactivated serum, and a virus which has been stored for some time.

It is, of course, conceivable that these neutralising antibodies react with some toxin or aggressin secreted by the virus and not with the virus itself. If that were so there would be no real difference between the inactivation of a virus and of a bacterium. But until such toxin or aggressin is demonstrated, economy of hypothesis makes us regard the antibody as reacting with the virus itself.

Serological Reactions other than Neutralisation.

Neutralisation of the virus is not the only property demonstrable in these immune sera. Complement-fixation reactions have been shown to occur by workers with the viruses of vaccinia, herpes, yellow fever, foot-and-mouth disease, dog distemper, and other viruses. Against vaccinia, further, a flocculation reaction has actually been used in the field as a method of diagnosis. Crusts of the lesions from cases of suspected small-pox are put up against a vaccinia-immune serum; a positive flocculation reaction suggests small-pox, a negative one chicken-pox or other disease as the diagnosis. But, just as with the corresponding reactions in bacterial diseases, we do not know what part, if any, those test-tube phenomena actually play in the immunity of the animal; nor whether the antigen concerned in them is the virus itself; nor whether the antibodies are identical with or run parallel with the neutralising antibodies.

It is also clear that, even if immune serum can inactivate a virus without the help of leucocytes, yet leucocytes *do play a part in destruction of virus*. Possibly they clear up and destroy virus which is prevented by its union with the antibody from getting inside susceptible cells. Normal rabbit leucocytes have considerable power to destroy vaccinia virus, and this destruction is helped by a heat-labile constituent of normal serum. But immune serum contains a heat-stable constituent which is still more effective in helping forward this destruction. The analogy with the mechanism of destruction of bacteria by phagocytes is obvious.

Cellular Immunity.

It has been maintained that immunity to viruses is a very special thing depending particularly on the cells and owing very little to antibodies; furthermore, that each tissue of the body—brain, skin, cornea, and so on—can develop its own immunity more or less independently of the rest of the body. These views have not met with much support in this country. It has been argued in their favour that a man vaccinated against small-pox is still immune at a time when antibodies can no longer be demonstrated in his serum; similarly, antibodies cannot be demonstrated by ordinary methods in guinea-pigs which are immune to foot-and-mouth disease as a result of vaccination. Instead of denying the existence of neutralising antibodies under such conditions it would seem more reasonable to suppose that the test for immunity to these viruses is more delicate than the tests available for detecting antibodies. An interesting light is shed by the tissue-culture experiments referred to earlier; in them it was found that herpes virus would grow in normal rabbit testis with normal rabbit serum, but not in immune rabbit testis with immune rabbit serum. On analysing this result by means of further experiment, it was found that immune serum prevented the virus from growing in normal rabbit testis, but that the virus would grow perfectly well in a culture of testis from an immune rabbit in normal serum. The immune serum was the important factor —it did not matter so much whether the cells came from a normal or an immune animal. However, one must not take up too extreme an attitude; cellular immunity doubtless plays some part.

The virus diseases which are not followed by lasting immunity are of particular interest. Herpes simplex, for instance, can recur in one subject again and again. Seventy-five per cent. of normal people appear to have antibodies to herpes virus in their serum, and those who are subject to recurring herpes seem all to have powerful neutralising sera; why, then, does their herpes keep recurring? Rabbits develop as good an immunity to herpes as to vaccinia; why *cannot* man? Possibly man is as solidly immune, on paper, as he is to other viruses, but the herpes virus *is able to circumvent* in some way the humoral or other defence mechanisms which are quite efficient *against other infections*.

Failure of Immune Serum to Affect Intracellular Virus.

It seems probable that an immune serum cannot neutralise a virus which is intracellular. Could it *do so*, it would be hard to explain how viruses could persist at all in animals with antibodies in their sera; and many viruses undoubtedly can do this. Many viruses can attack cells very quickly indeed, certainly within half an hour. In those tissue-culture experiments with herpes one type of experiment brought out two important points—first, the speed with which virus can attack cells; secondly, the fact that the immune serum cannot inactivate virus which has run for shelter to the safe harbour of the inside of a cell. Herpes virus was added to a culture of normal cells and immune serum was added half an hour later. It was too late; the virus had had time to invade the cells and proceeded to go ahead and multiply and form the typical inclusion bodies in spite of the antibodies which were now bathing the outside of the cell. Control experiments showed that the virus could never gain a foothold in the cell if the antibody was on the spot in time. Experiments on the living animal show the same thing. Immune serum can be put intradermally into a rabbit's skin and the exact spot marked. Virus inoculated into that exact spot five minutes later can produce no lesion. But if the virus is introduced five minutes before the serum it *can* produce a lesion; though it is true that this will be much smaller than that in a control site where no immune serum is injected. Here, again, the virus gets to work very quickly; the serum has got to be there first to do much good.

This sort of experiment has an obvious bearing on the possibility of serum-therapy in virus infections. It confirms the familiar clinical experience that serum is very potent as a prophylactic in some virus infections, but of much less use as a curative measure. It does not follow, however, that serum can do no good in therapeusis if the virus has once got in and infected a patient; I have suggested that it is probably unable to save a *cell* which the virus has once attacked. It may benefit the *patient* by limiting the number of cells which can be attacked and so controlling the disease. It is in this way that immune serum given during the incubation period of measles probably succeeds in aborting the disease.

HOSPITAL ALMONERS.—The annual report of the Incorporated Institute of Hospital Almoners records the taking possession of new premises in Tavistock-square and that the move has resulted in a great increase of work. The roll of students doubled during the year, and the number of hospitals appointing certificated almoners is steadily increasing. Thirty-nine such appointments have been made and 23 certificates granted, and at the close of the year there were 123 students in training. Lord Moynihan has become President in succession to Lady Bradford, and the council has decided that students without academic qualifications must obtain a University Social Study certificate during their course of training. Selection and advisory committees are already at work in Leeds and Liverpool, and others have been formed at Birmingham and Newcastle. It is hoped to standardise training and fees throughout the country.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

A MIDWIVES BILL.

ON the motion of Mr. R. Mulcahy, Minister for Local Government and Public Health, the Dáil last week gave a second reading to a Midwives Bill designed to amend the Irish Midwives Act, 1918. That Act, the Minister said, had helped to reduce the mortality due to childbirth very considerably, and the mortality for 1929 was the lowest in the records of the country—namely, 4·1 deaths per 1000 births. The average for the preceding ten years had been 4·88 per 1000. There were, however, certain loopholes in the Act of 1918, which it was now intended to close. Under the Bill any unqualified person who attended a woman in childbirth, unless such person could satisfy the Court that such attention was given in case of sudden and urgent necessity, would be guilty of an offence. Several deputies, of whom three were dispensary medical officers, drew attention to the low salaries paid to midwives employed in the poor-law service. It was also pointed out that, with the abolition of the "handy-woman," steps must be taken to increase the number of qualified midwives in the country, or there would be a shortage of service.

"OPTICAL BENEFIT."

Serious objection was taken on behalf of the medical profession last year to the methods sanctioned by the National Health Insurance Commission in the Irish Free State for the administration of the "optical benefit." This benefit, for which certain approved societies made provision, supplied glasses to members who required them, and the glasses were given on the advice of opticians, without any medical examination of the recipient or medical prescription. It was pointed out to the Commission at the time that such a practice involved two dangers. The absence of medical examination of those who complained of defective eyesight rendered it likely that many grave diseases of the eye would be overlooked, and their symptoms cloaked until serious damage had been done. On the other hand, the opticians were not slow to boast that their status had received the recognition of a Department of State, and the public were misled into thinking that opticians were a qualified class. It is now recognised by the Commission that these objections had substance in them, and it has been arranged that in future glasses will be supplied only on the prescription of a recognised ophthalmic surgeon. Arrangements have been made by which the services of ophthalmic surgeons will be available in all parts of the country.

COUNTY MEDICAL OFFICERS OF HEALTH.

In the Dáil last week, in answer to a question, the Minister for Local Government and Public Health was able to announce that county medical officers of health had now been appointed in 17 out of 26 counties in the Irish Free State. These counties are Carlow, Cavan, Cork, Donegal, Galway, Kerry, Kildare, Limerick, Louth, Mayo, Meath, Monaghan, Offaly, Roscommon, West Meath, Wicklow, and Wexford. In addition, there are three assistant medical officers of health in Cork, two in Donegal, and one in Galway.

THE BRITI at all ICAL ASSOCIATION AND DUBLIN.

The Leins union m. of the British Medical Association has alr suggestion, ts preparations for the annual and serum a meeting of the Association which is to be held in Dublin in 1933. The branch council has the cordial support of the Minister for Local Government and Public Health and of the Executive Council of the Irish Free State. The municipality of Dublin, through its Lord Mayor, Mr. Alfred Byrne, has also promised support, and the Lord Mayor has kindly offered the hospitality of the Mansion House for the use of the committees engaged in the arrangements for the meeting. The Universities and the Royal Colleges are also coöperating cordially, and no doubt will be equally ready to offer the hospitality of their buildings and premises. On April 15th a preliminary meeting of the profession of the Province of Leinster, together with representatives of various public bodies and many prominent laymen, was held in the Royal College of Surgeons, Dublin, to take the first steps toward organisation. The President of the Leinster branch, Prof. T. G. Moorhead, who is also President of the Royal College of Surgeons, was in the chair, and sketched the outlines of the necessary organisation. After him the Lord Mayor of Dublin was the principal speaker.

MEDICINE AND THE LAW.

Use of Quinine by Midwife to Induce Labour.

THE East Suffolk coroner lately held an inquest upon the death of a young married woman at Lowestoft. The jury found that the cause of death was hæmorrhage supervening upon the birth of her first child. The evidence, not disputed, was that a midwife had administered quinine to induce labour. She did this without medical supervision, using a prescription which a medical practitioner had employed in another case in which she had been engaged; he had told her that she could use the prescription at any time if she thought it necessary and that he regarded the treatment as absolutely safe. In answer to Dr. D. W. Boswell, the midwife admitted that it was not usual for the nurse to induce labour without consulting a doctor; she was not aware at the moment that she was giving the patient grs. 40 quinine; she had no idea of the amount. She did not realise at the time that she was breaking the rules of the Central Midwives Board. She admitted that Rule 19 forbade her administering medicine unless a note of it was put in the register; she had made no such entry in her register, but intended to do so later. The practitioner who had given the prescription stated that he had discussed with the midwife the safety of the method. When he told her she might use the prescription, he did not know that the rules forbade her giving anything but an aperient or ergot. In answer to the coroner he dealt with the amount of quinine which could safely be used. When using quinine in these circumstances he had known no case of post-partum hæmorrhage. Dr. Boswell, asked by the coroner, said it was recorded that quinine did occasionally produce serious hæmorrhage. In his summing-up to the jury, the coroner pointed out that there was not sufficient evidence to justify attributing the hæmorrhage to the administration of quinine. There was no question of a verdict of manslaughter, for the midwife had naturally believed and relied upon what a qualified doctor told her. The jury added to the verdict, already mentioned above, the rider that artificial induction of labour should only be produced under the strict supervision of a duly qualified medical practitioner. This opinion had already been expressed in his evidence by Dr. Boswell who explained that the prescription was a recognised method used in hospitals, but under strict medical supervision.

Breach of its rules is a matter which can be left to the Central Midwives Board to deal with. The midwife whose conduct formed the subject of the inquiry gave her evidence with frankness; she had eight years' working experience; more than one practitioner testified to her ability, and the jury's verdict absolves her. Two general observations may perhaps be added. Midwives who observe a treatment successfully applied by a doctor to one patient should not assume too readily that they themselves can safely apply it to other patients without supervision; secondly, prescriptions are not meant to be circulated like library books, least of all when a breach of the Central Midwives Board's rules is involved.

PUBLIC HEALTH SERVICES

PAYMENT FOR ACCIDENT CASES AT HOSPITALS.

UNDER Section 36 (2) of the Road Traffic Act, 1930, where any payment is made in respect of the death of or bodily injury to any person arising out of the use of a motor vehicle on a road, a sum not exceeding £25 shall be paid to cover reasonable expenses at the hospital where treatment has been given, provided that no charge has been made. Mr. W. Taylor, chief public assistance officer to the Surrey County Council, points out that the numerous accident cases admitted to Surrey municipal hospitals fall into two classes: (a) those belonging to the county, and (b) those who have a fixed place of abode in some other county or county borough. He suggests that all assistance granted to class (a) should be "on loan" under the provisions of Section 49 of the Poor Law Act, 1930. Each case reported to him would be considered on its merits, and in cases of probable long duration it might be advisable to make a charge and not a claim on the authorised insurer. Class (b) cases he would deal with under Section 80 of the Poor Law Act, 1930, which provides that the county or county borough in which they have a fixed place of abode should reimburse the council in full in respect of treatment. Credit would be given for moneys recovered from the authorised insurer. Such an arrangement would be a mutual one with other counties and county boroughs.

The Surrey Council has decided to adopt the procedure suggested by Mr. Taylor for a period of six months.

UNSOUND FOOD GIVEN AWAY AS PRIZES.

AT a meeting of the Metropolitan Boroughs Standing Joint Committee it was reported that unsound chocolates had been given away as a prize for a winning ticket at a recent entertainment in Islington. As a result of a visit paid to the stall by officials of the local authority, several hundred boxes of chocolates were surrendered as unfit for food and subsequently removed for destruction. The Metropolitan Branch Council of the Society of M.O.H.'s believes that a considerable amount of food is distributed in this way; complaints of unwholesomeness have from time to time arisen, but as the goods are not exposed or deposited for sale, Section 47 of the Public Health (London) Act, 1891, does not apply. The health committee of the Stoke Newington Borough Council is asking the London County Council to promote legislation, by means of a clause in a General Powers Bill, requiring that food given away as prizes or by tradesmen as gifts should, if intended for human consumption, be regarded as food exposed for sale under the section of the Public Health Act above mentioned.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 18TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 163; scarlet fever, 1376; diphtheria, 880; enteric fever, 36; pneumonia, 1313; puerperal fever, 45; puerperal pyrexia, 122; cerebro-spinal fever, 83; acute poliomyelitis, 5; acute polio-encephalitis, 2; encephalitis lethargica, 21; dysentery, 6; ophthalmia neonatorum, 131. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 21st–22nd was as follows: Small-pox, 208 under treatment, 8 under observation (last week 190 and 7 respectively); scarlet fever, 1234; diphtheria, 1568; enteric fever, 26; measles, 146; whooping-cough, 432; puerperal fever, 29 (plus 15 babies); encephalitis lethargica, 129; poliomyelitis, 2; "other diseases," 182. At St. Margaret's Hospital there were 19 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (1) from enteric fever, 55 (0) from measles, 4 (1) from scarlet fever, 34 (4) from whooping-cough, 35 (10) from diphtheria, 36 (7) from diarrhœa and enteritis under two years, and 110 (11) from influenza. The figures in parentheses are those for London itself.

The deaths from enteric fever occurred in Exeter, Nottingham, and Bradford. Eight deaths from meningococcal meningitis occurred in London, 4 under 1 year, 1 each from 1–2 years, 5–15, 15–25, and 25–35 years. Twelve fatal cases of measles were reported from Birmingham, 7 from Sunderland, 6 from Liverpool. Leeds reported 4 deaths from whooping-cough. Diphtheria claimed 9 victims at Liverpool, 4 at Birmingham. The 99 fatal cases of influenza outside London are scattered over 54 great towns: 9 were reported from Birmingham, 5 from Leeds, and 4 from Croydon.

The number of stillbirths notified during the week was 305 (corresponding to a rate of 42 per 1000 births), including 44 in London.

LANCASTER JOINT HOSPITAL DISTRICT.—Lancaster town council is applying to the Ministry of Health for a Provisional Order forming the boroughs of Lancaster and Morecambe and Heysham, and the urban district of Carnforth, into a united district to be called "The Lancaster and and District Joint Hospital District" for the provision, maintenance, and management, for the use of the inhabitants of the joint district, of hospitals for the reception of cases of infectious disease, including small-pox.

MIDDLESEX HOSPITAL.—The report for 1930 was adopted at a court of governors recently. The number of patients admitted during the year (471 beds) was 6751, and their average weekly cost £5 4*s.* 1*d.* The average stay was 22·40 days and the total cost of each patient was £16 14*s.* 4*d.* The number of new out-patients was 52,118, and the attendances, which numbered 234,869, showed a marked increase. With more beds opened and a larger out-patient department to maintain, the expenditure amounted to £129,967. The income, thanks chiefly to some large legacies, was £141,602, leaving a credit balance of £11,635. Prince Arthur of Connaught, who presided at the meeting, said that the reconstruction scheme is nearing completion, but that the money in hand is sufficient only to cover the cost of the framework, leaving approximately £245,000 to be found to finish the work.

CORRESPONDENCE

THE POST-GRADUATE HOSPITAL AND SCHOOL.

To the Editor of THE LANCET.

SIR,—In his letter last week "Simplicitas" states his case in a simple and restrained manner as befits his pseudonym. His doubts arise from the fact that the great object which the Ministry of Health has in view is to provide an efficient medical service under the National Health Insurance Act, and the doctors involved are those working under that Act. The Ministry is not primarily concerned with post-graduate education of the whole medical profession in the country and not at all with post-graduate education of the medical profession of the Empire. The proposals to provide a large post-graduate hospital on the lines of Vienna are far wider in their bearings than the actual needs of the Ministry.

Now it is quite obvious that the needs of the Ministry are urgent and as a considerable amount of time must elapse before a post-graduate hospital envisaged in the proposals which have been published can come into effect, it would be well if existing facilities were fully used. London is already well provided for as far as the Ministry is concerned. The Fellowship of Medicine would, I feel sure, be glad to coöperate, and at the West London Hospital every facility is already obtainable. Even now arrangements are being made with local national health insurance committees in several districts for their members to attend the West London, but the hospital practice is capable of being more widely used in this way.

I am, Sir, yours faithfully,

HENRY SIMSON,
Dean of the West London Hospital Post-Graduate College.

April 31st, 1931.

To the Editor of THE LANCET.

SIR,—It is, as "Simplicitas" says, "a splendid thing that a great post-graduate centre is to commence its activities in the metropolis," and it is to be hoped that the difficulties he mentions will not be formidable. In an English undergraduate school the student is taught new methods of diagnosis and treatment, and by the time he has finished his course he has had opportunities of practising them himself, having been shown how to do so under expert example and instruction. The same will apply to the post-graduate except that, having already learned what was taught in his day, he will be in the position of a senior undergraduate and will therefore be able forthwith to begin the study of new methods.

The difficulty which the English doctor finds in getting away is not insuperable; it will at any rate be easier for him to go to London than to Vienna. There are many post-graduate centres in Great Britain now. One is the Fellowship of Medicine. Last year considerably over 600 post-graduates took out the courses it offers; more than half of these came from Great Britain, most of them in general practice. As these figures are from one post-graduate centre only, the total number of practitioners in Great Britain taking post-graduate courses must have been large. They managed it somehow by getting a partner to do their work or by a locum tenens, just as others succeeded in obtaining a holiday.

I am, Sir, yours faithfully,

April 25th, 1931. W. HALE-WHITE.

To the Editor of THE LANCET.

SIR,—"Simplicitas" lays stress upon the difficulties of practitioners leaving their practices in order to undergo a course of post-graduate instruction. These difficulties can be overcome by adopting such a system as the holiday locum scheme run by the panel committee in connexion with practitioners on the London panel. By this scheme groups of doctors, varying in number from four to eight, arrange to act as locums for each other during absence on holiday. Each doctor pays into a pool five guineas for each week he is away, and his patients are given the list of members of the group to choose from when needing attendance. Payment out of the pool is made on the case value system, each individual patient (not each attendance) counting as one unit. In the case of practitioners on the panel the clerical work is undertaken by the panel committee. It should surely not present insuperable difficulties to arrange similar groups among other members of the profession.

I am, Sir, yours faithfully,

C. LUTHER BATTESON,
Medical Secretary, Panel Committee for the County of London.

Russell-square, W.C., April 28th, 1931.

INCUBATION PERIOD IN EPIDEMIC CATARRHAL JAUNDICE.

To the Editor of THE LANCET.

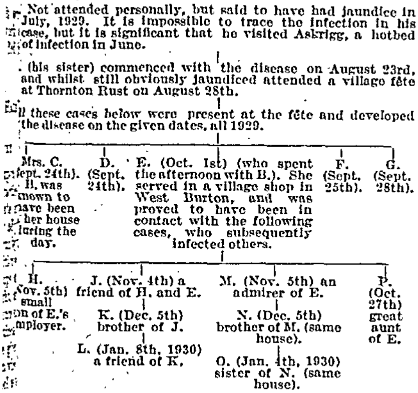
SIR,—I have read with great interest the account of an epidemic of catarrhal jaundice by Dr. J. Alison Glover and Dr. Joyce Wilson in your issue of March 28th (p. 722). There appears to be unanimity among recent writers as to its respiratory spread, but the above authors estimate the incubation period at about four days, a widely different view of the incubation period from that taken by Dr. W. G. Booth[1] and myself.[2] Personally I found it easier to trace the course of infection when the cases were few than when, as in the larger villages, great numbers of cases occurred. Surely a scattered country district gives a better opportunity of arriving at an incubation period than a school in which the cases come thick and fast, and it is impossible to say which case infected which.

I do not presume to explain the incidence of the cases in the later epidemic, beyond pointing out that the hiatus recorded in the authors' diagram from June 9th to July 13th, and also the case of the "little girl who developed icterus 20 days after leaving the town," suggest a long incubation period. But I should like to repeat in full the following striking sequence, which was outlined in my own paper, and which is strong evidence in favour of an incubation period of about a month. This is only one of several chains which occurred in the Wensleydale epidemic.

---

[1] Public Health, May, 1928.
[2] Brit. Med. Jour., 1930, i., 944.

ad which all support the claim of an incubation eriod of the same duration.



Not attended personally, but said to have had jaundice in July, 1929. It is impossible to trace the infection in his case, but it is significant that he visited Askrigg, a hotbed of infection in June.
. (his sister) commenced with the disease on August 23rd, and whilst still obviously jaundiced attended a village fête at Thornton Rust on August 28th.
ll these cases below were present at the fête and developed the disease on the given dates, all 1929.
Mrs. C. ept. 24th). B. was nown to ave been her house luring the day.
D. (Sept. 24th).
E. (Oct. 1st) (who spent the afternoon with B.). She served in a village shop in West Burton, and was proved to have been in contact with the following cases, who subsequently infected others.
F. (Sept. 25th).
G. (Sept. 28th).
H. Nov. 5th) small on of E.'s mployer.
J. (Nov. 4th) a friend of H. and E.
K. (Dec. 5th) brother of J.
L. (Jan. 8th, 1930) a friend of K.
M. (Nov. 5th) an admirer of E.
N. (Dec. 5th) brother of M. (same house).
O. (Jan. 4th, 1930) sister of N. (same house).
P. (Oct. 27th) great aunt of E.

These cases are the only ones which occurred in Vest Burton throughout the whole epidemic.

I am, Sir, yours faithfully,

W. N. PICKLES.

Aysgarth, Yorkshire, April 25th, 1931.

TREATMENT OF FUNCTIONAL ANOREXIA.

To the Editor of THE LANCET.

SIR,—It would be a pity to allow the paper in 'our last issue by Dr. Allison and Dr. Davies to go nremarked; for it places an emphasis that seems to ne unfortunate upon the dietetic and medicinal reatment of an important condition. Anorexia ervosa as originally described by Gull cannot be so are as they suggest; since T. A. Ross and R. Hutchison irst interested me in it I have seen two or three ases each year, without going out of my way to ook for them. It is often confused with mere loss f appetite in other conditions such as mental epression, but anorexia nervosa in the classical ense presents a clinical picture which is simply nmistakable, and in most cases curable as far as the ymptoms are concerned, not by elaborate dietary, ut by simple insistence on a sufficient intake of ood. The patients are nearly always young women I have not yet seen the symptoms in pure culture n a man) and unmarried. They complain (if you sk them, for they are usually brought by their elatives) of lack of appetite and amenorrhœa but of othing else; and they are more or less emaciated ut show no sign of organic disease. They are isually leading, if permitted, an ordinary life with pparent cheerfulness and apparently normal mentality n spite of a minimal intake of food which may ltimately reach vanishing point. Commonly they re at loggerheads with their family on the question f their nutrition.

Treatment consists essentially in removal from their family and isolation from visits and from correspondence; and in insisting that whatever they are given to eat must be eaten. To ensure this a reliable nurse is placed in charge with instructions to see that every feed is completely consumed. No special diet and no elaborate calculation of *calories* need be undertaken. The commencing diet should be only slightly in excess of that to which the patient has reduced herself; but it should be rapidly increased and by the third week dissatisfaction is expressed if a gain of five or six pounds a week has not by that time been reached. Bitter tonics, acid, insulin, thyroid, and gastric lavage are all alike superfluous. If the stomach has been labelled "atonic" or "dropped," some work to do, and some omental fat to lie on, will accomplish all that is necessary.

Although the condition has undoubtedly a psychological basis the above régime should be begun at once, and psychological exploration should not go deep at least till after food is being taken normally.

There are many other points of interest and importance both clinical and therapeutic but they would unduly expand a letter. In brief, régime and not minutiæ of diet such as are so ably described by Dr. Allison and Dr. Davies, is the important thing. If this is not realised it becomes much more difficult to restore these patients to health. These remarks of mine, however, do not apply to many varieties of illness often but erroneously labelled anorexia nervosa which are really examples of hypochondria, psychotic depression and the like.

I am, Sir, yours faithfully,

R. D. GILLESPIE.

Wimpole-street, W., April 27th, 1931.

SYPHILIS AND YAWS.

To the Editor of THE LANCET.

SIR,—The relationship of syphilis and yaws presents a problem of the greatest interest to those who have studied the latter disease but one to which the majority of your readers may have given little thought. Captain Butler in your last issue animadverts upon the common facts that many statements are repeated in medical literature which are not true or which are no longer accepted by the bulk of medical opinion. Among these he would place the view that yaws and syphilis are separate disease entities, and he boldy exclaims "to-day it is possible to say that yaws is purely *an artefact erected over* the disease syphilis. This statement is made with the hope that some 'dualist' will produce evidence to the contrary. There has been ample time for all such evidence to assert itself." He points out that "since the time of Sydenham and long before him there have been English and Continental observers who thought and *taught correctly about framboesia.* Berkeley Hill of English and E. Lancereaux of French physicians have shown how completely the yaws syndrome is identified with syphilis." I cannot help thinking that Captain Butler has been most unhappy in drawing inspiration from these two writers. Both wrote treatises upon syphilis, but neither had any *first-hand* knowledge of yaws, and in respect of this disease are guilty of that same fault in their writings of which Captain Butler complains. Their opinions were based upon the writings of others (Paulet for example) which they failed to interpret correctly. Their opinions upon yaws are absolutely valueless as will be apparent to anyone *conversant* with the older writers on framboesia. Lancereaux was not even aware that the words pian and yaws referred to the same lesion, and Hill says of sibbens (a non-venereal epidemic syphilis) that it much resembles yaws, a statement which is quite untrue.

Not very much has actually been written upon the unity or duality of these two diseases but (without entering the ranks of the duellists to cross swords with Captain Butler) I think it should be stated, lest Captain Butler's statement be given undue credence, that for the majority of those able to judge, yaws as a disease entity has appeared to withstand the onslaught of Captain Butler and others who hold opinions similar to his own. I think, moreover, that the dualists might quite fairly take up the opposite stand and express the view that the onus lay with Captain Butler to prove them wrong. As a non-partizan onlooker and without attempting to open a discussion I imagine he would be required to explain why no single case of absolutely undoubted syphilis has ever exhibited the typical pathognomonic florid eruption characteristic of yaws vouched for by an authority on frambœsia.

I am, Sir, yours faithfully,
HUGH STANNUS STANNUS.

Wimpole-street, W., April 25th, 1931.

DUROCAINE IN SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—In the current issue of the *British Journal of Anæsthesia* Dr. Bernard Johnson describes his practice with durocaine, a pseudo-hypobaric solution of novocain. He puts the patient in the reverse Trendelenburg position after injection with the idea of spreading the drug upward over the roots. He says:

> "In these cases it is usual to find that the lower limbs and the lower third of the abdomen become anæsthetised in about six minutes and that the remainder of the abdomen and lower thorax suddenly become anæsthetised after a varying period of time. It has been the writer's practice always to tilt the table to some degree of Trendelenburg position 15 minutes after the injection has been made. The reason for this delay cannot yet be stated, but it is probably due to some anatomical condition delaying the absorption of the anæsthetic."

In other words the novocain will not go up hill, but waits for the Trendelenburg position, for this mixture becomes a hyperbaric solution when diluted with cerebro-spinal fluid.

He injects 200 mg. of novocain into the spine of a child of 6 and up to 400 mg. in other cases.

> "In both these cases one, a child of 6 years who was given 2 c.c. of anæsthetic solution making it up to 3 c.c. with cerebro-spinal fluid, and the other an elderly fat woman with some myocardial degeneration, the respiration became snatching and no pulse could be felt at the wrist or in the preauricular division of the superficial temporal artery; the common carotid artery could just be felt; the eyes rolled upwards; there was extreme pallor of the face and lips, and in fact the picture was of imminent death."

Later he says: "In regard to the toxicity of the solution, it can only be said that no toxic symptoms were detected in any of the cases." It would be interesting to know what would be accepted as good evidence of poisoning in this clinic, for an upward trend of the eyeballs is usually regarded with apprehension even in lay circles.

Koster's theory is entirely invalid, based on the fallacy of direct medullary action, and false deduction from experiments on small batrachians and not much larger mammals. The respiratory centre can be paralysed with as much certainty by an overdose of novocain as it can be with chloroform. In the cases quoted it was badly affected as evidenced by the "snatching" respiration. It is difficult to understand how so improbable a theory could have gained so much ready acceptance. Before Koster and Pitkin clouded the issue with untenable and unscientific theories, Labat's dosage of novocain up to 150 mg. was accepted as a maximum requirement, and this should only be exceeded in heavyweight patients with long spines. Labat is now making a similar protest. An injection of 200 mg. into a child of should elevate the eyebrows of the onlooker as w as the eyeballs of the patient, for such dosage i beyond all reason. After such a recital is there need to contest the competence of gliadine to prev blood absorption?

Gum solutions were tried a generation ago a abandoned.

I propose to elaborate the proofs of my statemen at Eastbourne in July, but in the meantime so criticism seems to be called for.

I am, Sir, yours faithfully,
W. HOWARD JONES.

London, W., April 27th, 1931.

INSULIN AND PRESERVATIVE.

To the Editor of THE LANCET.

SIR,—We have been told that the Ministry Health intends introducing a Bill which wo necessitate the addition of antiseptic to those t peutic substances which are administered by inje into the tissues, when sold in containers from wh more than one dose has to be extracted. The val of such a regulation may appeal to some in the ca of sera and other fluids which form excellent cultu media for micro-organisms introduced accidentl and it will be remembered that the report of th commission which investigated the Bundabe disaster advocated this step in the case of a mixtu of diphtheria toxin and antitoxin.

However we would urge that there should be th most careful consideration and balancing of evide before insulin is included in such a regulation. I the case of sera which are administered very infr quently to a patient, the simultaneous administratio of a small amount of antiseptic can be of no cons quence; but it must be remembered that insul patients may be injecting themselves three times day for years and it would be rash to assert that th daily administration of a small dose of antiseptic such as tricresol, may not have some deleteriou action in the course of years. Some little time ago law was passed which made it illegal to poison th inhabitants of Great Britain by giving them smal doses of food preservatives, and it would certainl be illogical to make it obligatory for diabetics in th country to give themselves small doses of pois two or three times a day continuously.

Of course if cases of sepsis follow from the adminis tration of insulin which does not contain a preserva tive, the matter would be different, and one of o objects in writing this letter is to find out what ha been the experience of others in this connexio We would urge that further inquiries should be ma in all countries where insulin free from antisepti has been used and, only if evidence that cases o sepsis follow its use be obtained, that its sale in th country should be forbidden. The question al arises as to whether an ordinary solution of insuli is a suitable culture medium for extraneous bacteri provided the syringe and needle have not bee sterilised in alkali, which if introduced into th container might reduce the acidity of the insuli solution, but would lead to turbidity.

A precaution that might quite well be taken wou be to insist on this insulin being packed in colourles bottles and accompanied by instructions that, if th insulin does not look like perfectly clean water, i should not be used.

We are, Sir, yours faithfully,
O. LEYTON,
E. P. POULTON.

London, W., April 27th, 1931.

UNDULANT FEVER IN SHIPS.

To the Editor of THE LANCET.

SIR,—Surgeon-Captain Dudley will perhaps allow me to thank him for clearing up the diagnosis of "*Thalia* fever" After learning that enteric was not caused by dirt unless the dirt was infected by the specific bacillus, I had often wondered whence came the germ of the pyrexia in stuffy ships; I had not allowed for carriers. Surgeon-Captain Dudley explains that fever as due to overcrowding, with brucella infection superadded. This view, however, seemed to me excluded by the long incubation, the "spleen generally normal," and other clinical difficulties. But if we look on overcrowding as the special box, and the carrier as the match which sets the epidemic alight, ship epidemics like those in the *Thalia* in 1883 and the *Seaflower* in 1882 become intelligible. What is now wanted is an agglutination test of catarrhal and bronchitic cases in the Mediterranean to prove that brucella infection is prevalent, though no infected milk is drunk.

I would like to submit that, assuming that undulant fever in the Navy first appeared in the *Hannibal* and other ships at the time of the Crimean war, perhaps it came from the Crimea. Now that it can be exactly diagnosed by agglutination, the fever is always being reported from the east end of the Black Sea, from Azerbaijan, Armenia, Batoum, and quite lately[1] by Rudnew and Krumberg, from Rostoff-on-Don, at the top of the Sea of Azof, quite close to the Crimean Peninsula. May it not have existed there unrecognised in 1854? I am, Sir, yours faithfully,

W. E. HOME.

April 25th, 1931.

THE LATE MARGARET McMILLAN.

To the Editor of THE LANCET.

SIR,—I have been entrusted with the task of writing a record of the life and work of the late Margaret McMillan. It will assist materially if any of your readers will send to me any important letters, papers, or pamphlets they may possess. Personal memories would be most helpful. All documents will be returned in due course.

I am, Sir, yours faithfully,

ALBERT MANSBRIDGE.

38, High Oaks-road, Welwyn Garden City, Hertfordshire.
April 21st, 1931.

A SIMPLE METHOD FOR BLOOD CULTURE.

To the Editor of THE LANCET.

SIR,—With reference to Dr. Burnet's letter in your issue of March 28th (p. 729), I wish to state that I was not aware of the existence of a similar device. The essential part of my apparatus is the use of the Viskap which keeps the cap sterile until ready for use, and this, as far as I know, has not previously been used for the purpose described. I have examined the specification and I find that Dr. Burnet's patent No. 187900/22 is limited to a washer which consists of a layer of spongy rubber interposed between two ordinary impermeable rubber discs. As the apparatus described by me contains only a single rubber disc I am advised that anyone is entitled to use it without infringing any patent.

I am, Sir, yours faithfully,

J. E. McCARTNEY.

Southern Group Laboratory, Park Hospital,
Hither Green, S.E., April 27th, 1931.

TUBERCULIN-TESTING OF MILCH COWS.

To the Editor of THE LANCET.

SIR,—There appears to be a general impression that a large number of the cattle in tuberculin-tested herds react to the prescribed six-monthly test. This is not a fact. The figures on this farm, which is an ordinary dairy farm milking 80 cows and producing certified milk, are as follows. The herd was started in 1918 and the double intradermal test has been employed since this method was in general practice. Previously to this the subcutaneous test was carried out, but the former has undoubtedly proved the more efficient for the purpose of eliminating tuberculosis. It is, therefore, on the use of this test that these remarks are based.

In March, 1928, a licence for certified milk was taken out, and this demands a test every six months. The half-yearly tests have included all the cows in milk, dry cows, bulls, and in-calf heifers likely to come into the herd during the subsequent six months. These have averaged 120 for each half-yearly test. For two years we had not a single reactor, that is until March, 1930, when, owing to the fact that we were having a sale of a considerable portion of the pedigree stock because of lack of accommodation, all animals over ten months were tested, making a total of 156. Of this number, five failed to pass the test. One was a bought-in cow and the others were all first calf heifers. These heifers were known to have been in accidental contact with one or two possible sources of infection. In September, 1930, 106 animals were tested, and there was one reactor—a bought-in cow. In March, 1931, we had three reactors out of 120 animals tested. All three had been bought in since September, after passing the test. These reactors were in splendid condition, with no signs whatever of diseased udders.

If a herd is freed from tuberculosis, if no new animals are imported into the herd, and if there is no chance of contact with others not known to be free from disease, there is practically no risk of re-infecting the herd, providing that care is taken when purchasing hay and straw from other farms to ascertain that cattle have not had access to it, and that the water-supply is free from all possibilities of contamination.

I am, Sir, yours faithfully,

L. A. FOOT.

Hamberlins Farm, Northchurch, Berkhamsted.
April 22nd, 1931.

ROYAL VICTORIA HOSPITAL, BELFAST.—The annual meeting of this hospital was held on March 25th with the Duchess of Abercorn in the chair. The total admissions to the wards in 1930 amounted to 5947; new cases to the extern department numbered 55,665; the total attendance of old cases registered was 99,069. The observation wards were of great service; 1557 cases were treated there, of which 246 were subsequently admitted to the wards. The disbursements for the year were £61,894, and the receipts £60,775. A gratifying feature of the revenue account was the steadily increasing contributions from workpeople, which in spite of adverse trade conditions show an advance of £1408, realising the total of £25,327. A considerable amount of dissatisfaction was expressed that the National Radium Trust and the Radium Commission have not extended the distribution of radium on loan to hospitals in Northern Ireland, although the Royal Victoria Hospital fulfils all the conditions laid down for the formation of a radium centre. However, the hospital is developing a radium centre for Northern Ireland on the same lines as prescribed by the Commission in Britain, and through the generosity of the Viscountess Pirrie, and a few anonymous donors, a stock of radium valued at £3314 has been supplied. To supplement this the board has obtained a special loan of £4000 for the purchase of further radium, and delivery is expected in a few weeks. It is hoped that donations will be forthcoming to the radium fund to wipe out this indebtedness.

---

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

HOUSING (RURAL WORKERS) AMENDMENT BILL.

ON April 21st in the House of Commons Mr. ADAMSON (Secretary of State for Scotland) moved the second reading of the Housing (Rural Workers) Amendment Bill. He said that the object of the measure was to extend for a further period of five years the Housing (Rural Workers) Act, 1926. The principal Act arose out of representations by local authorities in rural areas to the effect that the grants for the erection of new houses were not wholly suitable to the circumstances of those areas. The local authorities urged that what was required was a grant towards the expenses of reconstruction and improvement of existing houses for farm workers and other persons of similar economic condition, the problem in many rural areas being not so much that there was a shortage of houses as that the existing houses required to be modernised and supplied with the recognised conveniences. Considerable advantage had been taken of the provisions of the Act of 1926, and it had been the means of providing improved and healthier housing accommodation for a large number of rural workers. Much of the work which had been done under the Act had consisted of the introduction of water, baths, and w.c.'s into houses; the provision of sculleries; the renewal of defective roofs and floors; the adoption of measures to do away with dampness, and the provision of larger windows to permit of better lighting and ventilation. The average grant given by Scottish local authorities had worked out in the course of five years at £86 per house, and in England the corresponding figure was £78 per house. Towards these grants the Exchequer contributed one-half in the form of an annual payment spread over a period of 20 years. Of the 33 county councils in Scotland, 32 had had schemes of assistance approved, and the remaining one had decided to adopt a scheme. In addition, schemes had been approved from 28 burghs. In England, he was informed, schemes had been approved from 297 authorities, including 46 county councils and 146 rural district councils.

Mr. GREENWOOD (Minister of Health) said when the Act of 1926 was being passed he did not believe, and he never had believed, that this method would prove to be acceptable on a very large scale to the local authorities of the country, but in so far as it could be used to make a practical contribution to the solution of the housing problem in rural areas, he thought the Government ought to give it their support. He had done what had been possible to encourage the adoption of the 1926 Act during the past few years, but he had been disappointed with the results. He had been induced to back a Bill for the extension of the 1926 Act because of the relative success it had met with in Scotland. For what it was worth, and within its narrow limitations, he hoped that the Act would be continued and that it might be more fully used.

SANIFYING OLD COTTAGES.

Lieut.-Colonel FREMANTLE said that this was one of the measures which showed the line along which they could usefully proceed in agricultural districts. The other view was that they should sweep away the old and get the new and the very best. As a medical officer of health he had heard people who were enthusiastic for good housing suggest that the old houses in villages should be swept away, and new ones built in their place, but he felt that that would involve a great deal of unnecessary waste. Cottages built in the middle of the last century were not up to date, but they could be made useful and sound by a certain measure of reconstruction. It must be bold reconstruction, and the 1926 Act provided for that. It was by an extension of that Act that they would be able to cope with the housing problem in rural areas. He was glad that the Labour Government had been converted to the usefulness of the measure passed by the late Conservative Government.

Major ELLIOT said that those who introduced the 1926 Act were only too pleased that it had now found favour in the eyes of some of its bitterest critics, and they were only too glad to support a Bill extending it for another five years.

After further debate the Bill was read a second time without a division.

SICK AND INFIRM VOTERS AT ELECTIONS

On April 22nd the House of Commons went into Committee on the Representation of the People (No. 2) Bill. Sir R. YOUNG (Chairman of Committees) was in the chair.

On Clause 6 (Restriction on the use of vehicles at Parliamentary elections) Major ELLIOT moved an amendment to insert the following: "Provided that nothing contained in this section shall, subject to the provisions of the Corrupt and Illegal Practices Prevention Act, 1883, prohibit any person from conveying to the poll any elector who by reason of age, bodily infirmity, or other incapacity would be unlikely to vote unless conveyed to the poll." He said that it would be agreed that the small number of persons who were covered by this subsection ought to have every possible consideration. They all knew how difficult it was to arrange for cars for these persons who were found in the course of an election to be sick or infirm or liable not to vote unless conveyed to the poll. It was those emergency cases arising on polling day which would be ruled out by the very stringent provisions of this clause unless some step was taken to meet the point. The proposed proviso might not be ideal, but it was an attempt to deal with the situation.

Lieut.-Colonel FREMANTLE said that the probability was that there would be very few motor-cars over which the returning officer would have control, and if, as was frequently the case, in any particular constituency there might be one or more institutions containing between them hundreds of electors who were bodily infirm and unable to go to the poll on foot, the returning officer might not have sufficient motor-cars to accommodate them. There were many electors who would be quite prepared to lend motor-cars to take such people to the poll, but they would not give their cars to the pool under the returning officer. If this proviso was not allowed the Government would be branded in many constituencies with having deprived the sick, the aged, and the infirm of the possibility of exercising their votes.

Mr. CLYNES (Home Secretary) said that he quite admitted that there was something in the idea of the amendment. It might well be that there was in every Parliamentary constituency a group of persons quite unlike the general body of the electors in such a condition of infirmity as to be physically disabled from going to the poll like the rest of the electors and in such a condition as not to feel quite safe going with groups of other people, and who would therefore desire to be conveyed in an ordinary private way by friends of their own who had a motor-car at their disposal. He could assure Major Elliot that the Government would consider the matter sympathetically before the Report stage in order to see if some words could be devised to cover what the hon. Member had in mind.

After further debate, the amendment was negatived by 250 votes to 142.

WORKMEN'S COMPENSATION BILL.

On April 24th the House of Commons passed the third reading of the Workmen's Compensation Bill. This is a measure which has been introduced to deal with difficulties in the law of workmen's compensation which have arisen owing to the judgment of the Courts in the case of Bevan *v.* Nixon's Navigation Company. The effect of that judgment was to cut down materially what had hitherto been regarded as the scope of the Act of 1925 which consolidated the Act of 1923. Up to the time of the Bevan *v.* Nixon decision it was thought that an employer was bound to find work for an injured workman or to provide compensation. The Bill is made retrospective to Jan. 1st, 1924, and under its provisions the Bevan *v.* Nixon's Navigation Company judgment will not apply in respect of cases which happened on or after that date.

THE BUDGET.

In the House of Commons on April 27th Mr. SNOWDEN, the Chancellor of the Exchequer, made his annual Budget statement. In the course of his speech he stated that the estimates of expenditure for 1931–2 totalled £803,366,000, as compared with an estimated revenue of £766,000,000. This left a gap to be bridged of £37,366,000, which was a deficit greater than that of last year's actual deficit of some £14,000,000. This result was mainly accounted for by the need of providing £12,000,000 more for de-rating. Provision had also to be made for £30,000,000 for transitional unemployment benefit. To meet this deficit £20,000,000 would be provided by a reduction of that amount in the exchange account, following the Hague Agreement and the institution of the Bank of International Settlements. In 1931 income tax under Schedules B, D, and E in the case of certain taxpayers, instead of being paid in two equal instalments, would be paid in instalments of three-quarters and one-quarter on Jan. 1st, 1932, and July 1st, 1932, respectively. Taxpayers concerned in this change will be individuals and firms engaged in trades, professions, or husbandry and employees. The result would be that the Exchequer would gain an extra quarter of a year's tax within the current financial year. The estimated yield was £10,000,000. There would also be an increase in the duty on oil from *4d.* to *6d.* as from April 26th. The proposed increase would still leave petrol no dearer than it was before March, 1931, and lower than it was before September, 1930. It would be slightly less than it was after the original *4d.* duty was imposed. It was expected that the increased duty would not appreciably affect consumption. The estimated yield was £7,500,000 in the current year, and over £8,000,000 in a full year. The balance-sheet, therefore, left a nominal margin of £134,000. No provision was made for supplementary estimates. If prosperity returned a margin might be found in an excess yield from taxation above the estimates he had forecasted. Apart from this, gaps would have to be met by economy in national expenditure. Provision would be made in this year's Finance Bill for (*a*) a valuation, and (*b*) the imposition of a tax on land values. It was hoped that the valuation would be completed within two years of the passing of the Bill, and would therefore be available as the basis on which to charge an annual tax for 1933–34 and subsequent years. The tax would be at the rate of 1*d.* per £ of land value.

PHARMACY AND POISONS BILL.

In the House of Lords on April 27th the Pharmacy and Poisons Bill passed through Report.

YARMOUTH NAVAL HOSPITAL BILL.

The Commons amendments to the Yarmouth Naval Hospital Bill were considered and agreed to.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 22ND.

Pensions for Neurasthenia and Shell Shock.

Mr. PRICE asked the Minister of Pensions whether, in view of the effect on the nerves of ex-Service men suffering from shell shock and war neurasthenia of the uncertainty as to the continuance of their pensions, he would consider the question of making these pensions permanent after they had been in receipt of them for the last eight years.—Mr. F. O. ROBERTS replied: Of the total number of pensions in payment for neurasthenia and shell shock about 90 per cent. have already been made permanent. I can assure the hon. Member that the possibility of making final awards in the remaining cases will be constantly kept in view. To make such awards in cases which are not medically suitable for them would not be in the best interests of pensioners generally.

Child Mortality in Hong-Kong.

Mr. GRAHAM WHITE asked the Under Secretary for the Colonies whether, seeing that some official information was available with regard to 1724 out of 1851 dead bodies of children of three years of age and less picked up in the streets of Hong-Kong during 1929, he would call for a report upon the remaining 127 dead bodies; and whether in any case death was due to violence.—Dr. SHIELS replied: Of the 127 bodies, 98 were those of children over three years of age, and 29 were infants of unknown sex. The Governor was requested by my noble friend to state whether in any of the 1851 cases reported for the year 1929 death was due to violence, and he has replied that in no case was there found to be any evidence of violence. In 521 cases of children of three years or under the cause of death was found to be small-pox.

Imported Milk.

Miss PICTON TURBERVILL asked the Minister of Agriculture whether he would inform the House how much per cent. of the milk consumed in Great Britain was imported, showing condensed milk and imported dried milk separately.—Mr. W. PALING (Lord of the Treasury) replied: On the basis of estimates for the years 1924 to 1927, contained in "The Agricultural Output and the Food Supplies of Great Britain," 1929, which are the latest complete figures available, it is calculated that after converting preserved milk into its estimated equivalent in liquid milk, approximately 8 per cent. of the milk consumed in Great Britain is imported, of which condensed milk accounts for rather over 7 per cent., and milk powder for rather under 1 per cent.

THURSDAY, APRIL 23RD.

Standard of Imported Milk Products.

Mr. OSWALD LEWIS asked the Minister of Health whether his attention had been called to the fact that the importation or sale of milk preparations not containing prescribed minims of milk fats was prohibited in 24 countries in the British Empire and in 20 foreign countries; and whether he would consider the desirability of promoting similar legislation in the interests of public health in this country.—Mr. GREENWOOD replied: I am aware of the fact stated, but I do not think it is necessary in the interests of the public health to introduce legislation for this country similar to that referred to.

Mr. LEWIS: Why should we be satisfied with a lower standard in this country?

Mr. GREENWOOD: I am not satisfied that it is a lower standard.

Sir A. STEEL-MAITLAND: If a minimum of butter-fat is prescribed for fresh milk should there not be a minimum for preserved milk?

Mr. GREENWOOD: The point of the question related to public health, and I understand that there is no reason on that account for altering the law.

Rejection of Army Recruits.

Mr. TINKER asked the Minister of Health if he was aware that from October, 1929, to September, 1930, 66,717 men offered themselves for service in the army, and 52 per cent. were rejected on physical grounds; and if his department had done anything to find out what were the physical disabilities, so that steps could be taken to advise the House of Commons on adopting measures to improve the physical standard of our people.—Mr. GREENWOOD replied: I understand that the facts are as stated in the first part of the question. As regards the second part, my department has obtained full information on this subject from the War Office, and it will receive my careful consideration.

Earl WINTERTON: Has the right hon. gentleman seen a manifesto issued by a number of doctors stating as one of the reasons for this deplorable physical condition and these deficiencies as to health and teeth, that they are due to the artificial foods eaten in this over-industralised country; and will the right hon. gentleman have that report considered by the appropriate experts in his department?

Mr. GREENWOOD indicated assent.

Approved Societies and Voluntary Hospitals.

Lieut.-Colonel FREMANTLE asked the Minister of Health the approximate estimated cost of the services rendered by voluntary hospitals to members of approved societies; and what contributions were made by approved societies to the funds of voluntary hospitals in return for such services.—Mr. Greenwood replied: No material is available to enable any estimate to be made of the cost of the services rendered by voluntary hospitals to members of approved societies. The total amount allocated by societies in England in payments to hospitals under schemes consequent upon the second valuation was at the rate of about £300,000 per annum. Schemes based on the third valuation are at present in operation in societies covering only about one-quarter of the total insured population, but under those schemes the annual amount allocated to hospital benefit has been increased by about 14 per cent. above that previously allocated.

Lieut.-Colonel Fremantle asked the Minister of Health if, in view of the fact that last year University College Hospital treated over 2000 members of approved societies at a cost of £22,000, towards which the societies contributed only a little more than £3000, and that of 124 of these societies whose members were admitted to the hospital 44 contributed part of the cost and 80 contributed nothing, he would take steps to bring the claims of the voluntary hospitals to the notice of approved societies in connexion with the allocation of their disposal surpluses.—Mr. Greenwood replied: The attention of all approved societies has already been directed to the provisions of the National Health Insurance Act, under which they are empowered to allocate part of any disposable surplus disclosed on valuation to the making of payments to hospitals in respect of the maintenance and treatment of their members therein.

Lieut.-Colonel Fremantle: Is it not possible for the right hon. gentleman to draw the attention of the societies to the fact, which they probably do not realise, that they are getting very much more from the voluntary hospitals than is covered by the small contributions which they make? I am sure they wish to pay their own way.

Mr. Greenwood: I am prepared to do what I can, but I have no power to enforce it.

Mr. Gossling: Is the right hon. gentleman aware that the great bulk of the workpeople who are compulsorily insured are contributing week by week to the Hospital Saturday Fund.—No answer was given.

Rheumatic Diseases.

Mr. Graham White asked the Minister of Health if, in view of the new efforts being made to combat the evils arising from rheumatic diseases, he would now consider the advisability of setting up an advisory committee on rheumatism on the same lines as the advisory committee on cancer.—Mr. Greenwood replied: I have given careful consideration to this suggestion and have come to the conclusion that I should not be justified at the present time in setting up such a committee as is mentioned in the question.

Factory Medical Officers.

Dr. Hastings asked the Home Secretary the number of persons employed in factories and the number of full-time medical officers in the factory service.—Mr. Short replied: According to the Workmen's Compensation returns for 1929—the last year for which figures are available—the number employed was 5,531,322, including 347,480 outside workers. As regards the latter part of the question, the only whole-time official appointments are the Medical Inspectors of Factories who now number eight. The certifying and other surgeons who are appointed under the Factory Act for particular duties and who number about 1800 are part-time posts.

Veterinary Research Institute.

Mr. Lees asked the Minister of Agriculture whether his attention had been called to the financial situation of the Veterinary Research Institute of Camden Town; and whether he would be prepared to recommend to the Chancellor of the Exchequer that a special grant be given to keep the institute in reasonable efficiency.—Dr. Addison replied: Yes, Sir. I am well aware of the financial position of the Animal Pathology Research Institute attached to the Royal Veterinary College at Camden Town. A scheme for the development and research in animal diseases upon a considerable scale is in an advanced stage of preparation and will, I trust, be sanctioned and brought into operation at no distant date.

Medical and Dental Scholarships.

Dr. Hastings asked the President of the Board of Education whether any maintenance scholarships were provided by his department to secure for children from the secondary schools training for the medical and dental professions.—Mr. Lees-Smith replied: No scholarships provided by the Board of Education are specifically earmarked for students proposing to be trained for the medical and dental professions; but 300 State scholarships are offered annually to pupils from grant-aided secondary schools to enable them to take up courses at Universities for Honours deg including those in Medicine and Dentistry, or preliminary science courses.

MONDAY, APRIL 27TH.

National Health Insurance Funds.

Mr. Grace asked the Minister of Health whether he w *give the figures of the accumulated funds of* appro societies for the last three available years, and the respe amounts which had been invested by or on behalf of appro societies for those years.—Miss Lawrence (Parl. Secretary to the Ministry of Health) replied: The lated funds of approved societies in Great Britain amo to £115,500,000 at Dec. 31st, 1928: £113,000,000 Dec. 31st, 1929; and £114,000,000 at Dec. 31st, 19 The amounts invested by or on behalf of approved have been £1,000,000 for 1928; £1,000,000 for 1930. 1929 investments were realised to the amount of £2,500,

Public Vaccinations.

Mr. Freeman asked the Minister of Health whether would furnish a statement showing the number of vaccinations and re-vaccinations, respectively, carried in England and Wales in each year during the last ten yea and the expenditure incurred out of national and lo funds respectively, together with the number of dea from small-pox during each of the years in question. Mr. Greenwood replied: The following statements these particulars for the last ten years for which compl figures are at present available: (1) Statement showing th number of public vaccinations and re-vaccinations, and th number of deaths from small-pox, in each of the ten yea 1920 to 1929.

Year ended Sept. 30th.	Number of successful primary vaccinations.	Number of successful re-vaccinations.	Deaths from small-pox in the year end Dec. 31st.
1920 ..	258,996	12,898	30
1921 ..	245,154	26,775	5
1922 ..	223,838	12,887	27
1923 ..	415,519	316,641	7
1924 ..	331,522	89,600	13
1925 ..	270,755	40,939	9
1926 ..	279,721	54,221	18
1927 ..	305,005	113,117	47
1928 ..	320,687	163,918	53
1929 ..	258,986	104,397	39

(2) Statement showing for each of the ten years 1919-2 to 1928–29 the total expenditure of *local authorities* o vaccination, the receipts from Government grants, an the balance of the expenditure met out of rates, &c., togeth with the total cost of the Government lymph establishment

Year.	Total expenditure.	Receipts from Government grants.	Balance falling on rates, &c.	Government lymph establishment.*
	£	£	£	£
1919–20	133,265	9,247	124,018	11,973
1920–21	183,789	8,862	174,927	20,091
1921–22	172,558	10,323	162,235	16,211
1922–23	191,416	10,244	181,172	14,489
1923–24	235,677	11,753	223,924	16,553
1924–25	182,077	3,050	179,027	11,205

1926–27	179,066	8,338	170,728	14,356
1927–28	190,754	8,853	181,901	15,321
1928–29	191,643	10,522	181,121	15,377

* Of the total cost of the Government lymph establishme 15 to 20 per cent. in each year is attributable to the cost lymph supplied to the service departments.

Glasgow Ear, Nose and Throat Hospital.—Lord Provost Kelly, presiding at the fifty-first annu general meeting of the hospital, said he was glad for on to be speaking for an institution in which there was n deficit for the preceding year. The new building had onl been opened for four years, but its resources were alread taxed to the utmost and plans were being considered f an immediate further extension. The necessary groun had been obtained through the generosity of an anonymo donor, and funds were now required to provide the buildin It was a sad feature of the work of such a hospital that s many children required treatment; 4602 under 15 yea of age were treated during the previous year, and the were indications that a tremendous amount of work was sti necessary in connexion with child health in Glasgow.

HOSPITAL OUT-PATIENTS.

THE PRACTITIONER'S POINT OF VIEW.

AT a meeting of the St. Pancras Division of the ritish Medical Association on April 28th, Dr. W. A. M. VAN took the chair and explained that the gathering as called to consider the B.M.A. Council's recent port on out-patients.[1] The question vitally affected e general practitioner, whose proper work was being ken from him by the increasing competition of the eat voluntary hospitals. It was impossible for ose hospitals to give adequate treatment or to get e best results from their material and equipment hen they were snowed under by an unmanageable mber of out-patients; neither was time and fficient opportunity given to students to derive the st benefit from the cases. A hurried examination the patient was followed by prescription of a rtnight's medicine, a state of affairs which reflected great credit on either the hospitals or the profession. n object of this meeting was to help the B.M.A. end this state of affairs and replace it by something tter. Members of hospital staffs had been invited attend, so that all sides could be discussed. The nclusions and recommendations of the Council ere as follows:—

1. That a large amount of the work at present undertaken the out-patient departments of voluntary hospitals is necessary and can be reduced.

2. That the volume of work at present undertaken at e out-patient departments is such that the best use cannot made of the services of the members of the hospital affs.

3. That there is considerable wastage of public money and professional time and skill.

4. That the existing internal and external checks at esent employed are not sufficiently stringent.

5. That further checks and safeguards should be tablished at all voluntary hospitals before treatment is dertaken at the out-patient department.

6. That the primary object of the out-patient department should be for consultation.

7. That while there should be adequate opportunities r consultation purposes between the private practitioner d members of the visiting medical staffs at out-tients departments, practitioners should not countenance e use of that department by their patients, except in the ays laid down in this memorandum.

8. That the casualty department should be available in y emergency.

9. That only such treatment should be given at the partment as cannot in the best interests of the patient obtained elsewhere under the usual arrangements as tween private practitioner and private patient, or under ntract arrangements.

10. That cases admitted for treatment at out-patient partments should be reviewed at regular intervals by the edical staffs.

11. That no person, except in cases of emergency, should accepted for treatment as an out-patient at a voluntary ospital unless he brings a recommendation from a private edical practitioner, a provident or other dispensary, a ublic clinic, or from a public assistance medical officer of local authority.

12. Where out-patient departments are shown to be ecessary in connexion with council hospitals, the rinciples applicable to voluntary hospitals, as set out in he preceding paragraphs, should apply.

THE HOSPITAL'S ATTITUDE.

Major R. R. GARRATT (Secretary, Royal Free ospital) said this subject had been before the uthorities of his hospital for a long time. The ospital tried to be of the greatest possible usefulness to the public, and it had appointed a subcommittee to ascertain how this and other problems connected with the out-patient department could best be served. The demand for hospital treatment and care came from the patient himself, and that being so, the hospital authorities were unable to keep him away. Patients felt that at hospital they could be sure of having a more thorough examination than at the hands of the general practitioner. Therefore the matter rested a great deal with the members of the profession. To obtain hospital advice and treatment, patients seemed quite willing to wait a considerable time. No hospital wished to have its out-patient department overcrowded with chronic cases. In every well-organised hospital every effort was made to refer patients back to their own general practitioner, but patients could not be forced to go back to him. Also, patients were encouraged to bring a letter from their doctor, for he agreed that the prime function of the out-patient department should be consultative. Usually it was found that the panel doctor was not one who was ready to give a patient a letter to take to a particular hospital. At the teaching hospitals there must be adequate clinical material, and the quality of the material was not known until an examination had been made. If there could be devised a simple system of reference back to the practitioner from the hospital, the Royal Free Hospital would support it.

The LADY ALMONER of the Royal Free Hospital said that consideration for the patients must come first, and for their comfort the numbers must be reduced. It was now more important than ever that the hospitals should be consultative centres. About half the panel patients who came to hospital did not bring letters.

Miss ELIZABETH BOLTON said that to many very poor patients a levy was a great hardship.

Dr. H. S. BURNELL-JONES thought no out-patient should be seen unless he presented a letter from his doctor. The sympathetic coöperation of hospital staffs was necessary for dealing with this question.

Mr. JENNER VERRALL spoke on the special department aspect. It was the exception, he said, for a patient to reach his department at the Royal Free Hospital without presenting a letter from his doctor, and he believed that was true also of the other special departments of the hospital. He never inquired whether a patient was a panel patient. He made a big effort to personally answer all the letters brought by patients; but it was difficult, and there was a great need of clerical assistance. He expressed a strong objection to the suggestion behind recommendation No. 10 that cases should be reviewed at regular intervals by the medical staffs. Surely that was the practice at every hospital?

Mr. J. WIGG contended that some 80 per cent. of the population were provided in some way with medical service, and the solution of the present out-patient difficulty lay largely in the hands of the practitioners in the district. A member of his staff had suggested that blocks of forms should be used, perforated down the centre, one side containing particulars of the patient to be sent with him to the out-patient department, and the other retained by the practitioner.

TOO MANY OUT-PATIENTS.

Dr. PEARSON said that nowadays patients got the best available service; the question was whether it was very costly, or whether people should be allowed to attend out-patient departments as much as they did. Certainly the out-patient department should be used more for consultative purposes;

---

[1] See Brit. Med. Jour. Supplement, Fe[illegible] 21st.

[illegible] Library

but if the attendances were cut down very much, the educative value of the institution would be largely destroyed. The only real solution that he could see was to insist that each patient should bring a doctor's letter.

Dr. TURNER spoke of the large demands made on hospitals by members of the Hospital Saving Association. They paid 3*d*. a week against the possibility of needing hospital treatment, and mostly seemed bent upon getting their money's worth.

Dr. OWEN THEOBALDS said that many people were now drifting into hospitals who formerly would not have thought of doing so, and in many cases—he gave examples—they were receiving free what they could well afford to pay for in private consultation.

Mr. A. C. ADAMS (Secretary, National Temperance Hospital) spoke of the valuable work done by almoners in checking the abuse of hospitals. At his hospital every effort was made to eliminate nonessential cases as much as possible. The Hospital Saving Association and other kindred bodies rendered a solution of this subject more difficult than it would otherwise have been.

Dr. P. P. DALTON warmly resented the veiled attacks which had been made on panel practitioners; it had been said that when patients brought up Hospital Saturday Fund letters they were carefully scrutinised, and panel patients were returned to their doctors. Yet the panel doctor was the personal family doctor; he was not a separate entity. In London at the present time public charity was being grossly abused. In all directions money was being collected for charitable purposes—i.e., for the destitute poor—and was being largely spent on those who could not only afford private fees, but were sometimes better off than those who subscribed. The general practitioner was being stamped out of existence, and when the process was complete, who would be at the call of the family for medical attendance, for confinements, &c.? Hospitals would not take on that work. As much money was being subscribed for hospitals as before the war. The grants to hospitals from the King's Fund were not according to the number of cases they cured, nor according to the number of cases passing through their beds, but according to the number of out-patient attendances they scored; so that if a hospital had its out-patients coming twice as often, or had twice as many out-patients, it would receive an increased grant. Practitioners could not help regarding themselves as competitors with the hospitals, and he urged coöperation with hospital staffs as a solution of the difficulty.

THE PATIENT'S RIGHTS.

Dr. GEOFFREY EVANS said the B.M.A. thought of the doctors first, and it made a fundamental mistake in its policy in not thinking of the public first. If it did it would strengthen its position. Patients must be allowed their freedom. He disagreed with the idea that patients should not be seen at hospital unless they came armed with a letter from their doctor. But he wrote a letter about every patient he saw. Dr. J. H. Drysdale gave him this advice: "You sit in your room and see people who ask your advice; you use your discretion as to whether you give your opinion; and you can say to the patient 'before I give my opinion I will talk your case over with your doctor.'" Doctors worked for people who appreciated their work. If the B.M.A. tried to tie people to their doctors and they succeeded in it, they would collapse. Recommendation No. 11 he regarded as a scandal; it was ethically wrong. When he saw patients he did not inquire about their income, he only wanted to know what their complaint was, and, having ascertained that, he did his best for them. He disliked the statements about doctors being in competition with hospitals. It was not the first object of teaching hospitals to be consulting centres; that was the second object. Their first object was the teaching of the profession and the study of medicine.

CANCER OF THE LIP, TONGUE, AND SKIN.

A MEMORANDUM FROM THE MINISTRY OF HEALTH

THE eighth of a series of memoranda on cancer being issued from the Ministry of Health for the guidance of local authorities has just appeared. This memorandum relates to cancer of the lip, tongue, and skin, and is based largely upon an examination, including a statistical analysis of such matters as lend themselves to the process, of available published writings on cancer of these organs.[2] Malignant growths in these three organs have in common a character which may facilitate their early recognition or even preventive treatment. This character is the persistence prior to the development of the cancer of an apparently harmless or at least noncancerous condition. Advantage can be taken of this warning only if suitable instruction and advice is provided for the community.

This group of cancers provides opportunities for the application of preventive medicine, in the modern sense, in three aspects: (1) Prevention or removal of conditions associated with causation. (2) Curative treatment of abnormal conditions likely to develop the cancerous change. (3) Surgical removal, by operation, radiation, &c., of the actual cancer at an early stage.

Some of the preventive measures available concern the education of the community to the realisation that certain habits, such as smoking or chewing tobacco, or picking or scratching warts or moles may set up "chronic irritation" of some parts of the body, notably the skin or the orifices, and that any chronically irritated area which after a time shows a marked change should be submitted to medical examination and treatment without delay.

Avoidance of syphilitic infection, attention to oral hygiene, elimination of environmental factors which may adversely affect the health of industrial workers are also mentioned.

Special measures are advised in relation to substances used in industry, such as certain oils and tar, tar derivatives, arsenic and soot which may contain carcinogenic agents, and to workers who come into contact with them.

It is noted that the avoidance of unnecessary exposure to X rays and the adoption of suitable precautions has resulted in new cases of the preceding inflammatory condition of the skin becoming very rare, and it is anticipated that this variety of the disease will in due course be eliminated.

BRITISH ORTHOPÆDIC ASSOCIATION.—The Robert Jones medal and association prize of this association has been awarded for 1930 to Mr. Harold Clifford Edwards for an essay on Injuries of the Tendons and Muscles.

OBITUARY

ENRY PERCY DEAN, M.S. Lond., F.R.C.S. Eng.,

CONSULTING SURGEON TO THE LONDON HOSPITAL.

We regret to record the death of Mr. Percy Dean ich occurred at his house in Abinger-road, Bedford rk, on April 14th in his sixty-seventh year.

Henry Percy Dean was born in London and educated University College, London, and at the medical hool at University College Hospital. He disiguished himself as a student, being scholar and edallist in the University in physiology, holding e of the surgical exhibitions, and obtaining the gold edal in anatomy. He graduated as B.Sc. in 1884 d as M.B., B.S. four years later, while he took the .S. Lond. in 1889 and the F.R.C.S. Eng. in the me year. Having held the usual residential posts became assistant surgeon at the London Hospital 1892 and obtained charge of beds as full surgeon 1899. As hospital officer and as teacher of operative rgery at "The London" he made a distinct mark, hile he also had a well-deserved reputation as a ediatrist, due to his long connexion with the ueen's Hospital for Children. For a considerable riod he was also a surgeon to the Royal Northern ospital.

Dean was a clear and well-informed writer, and his ntributions to medical literature, though neither any nor long, were definitely valuable. In his rlier writings his physiological equipment was vious. On the innervation of the pulmonary ssels he contributed a paper to the Proceedings of e Royal Society in 1889, and he wrote on the same bject in the *Journal of Physiology* a few years later. the Proceedings of the Neurological Society he ade an interesting contribution upon the temperare of the two sides of the body in cerebral comession, a paper which was followed by one published the *Journal of Pathology* on Cerebro-spinal Pressure. The Lancet he communicated an account of a ccessful operation for cerebellar abscess. He was so author of the articles on injuries and diseases of e head in Treves's "System of Surgery," and he lited Heath's "Injuries and Diseases of the Jaw."

Dean was still under 50 when he retired from spital practice, being made consulting surgeon the London Hospital in 1913, a position which he so occupied at the Queen's Hospital for Children. e was a Fellow of University College, London.

HE LATE MAJ.-GEN. G. F. A. HARRIS, I.M.S.

An old colleague and friend writes: "I would be ad of your permission to supplement the account the official career of General Harris in The Lancet April 25th, by a reference to his personal qualities. istinguished alike in his profession and in the rvice to which he was devoted, he earned the nfidence and esteem of all who had the good fortune serve with him or under him. After his retirement ward he continued to take an active interest in edical and service questions. During the late war e returned to duty and worked on an Army medical oard and as an inspector of V.A.D. hospitals. There re few whose loss will be more generally deplored y brother officers and friends."

Tyrrell Cottage Hospital, Ilfracombe.—An ray department has just been opened at this institution at cost of £650.

MEDICAL NEWS

University of Cambridge.

On April 24th the following degrees were conferred:—

M.D.—H. V. Coverdale (*by proxy*), and G. K. Kirwan-Taylor.

M.B. & B.Chir.—M. A. Robertson, W. V. Howells, J. J. Keevil, I. B. Morris, and J. A. Pocock.

M.B.—Gwyn Rocyn-Jones.

B.Chir.—G. K. Kirwan-Taylor.

At recent examinations the following candidates were successful:—

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

Part I.—Gilbert Maclean, and W. S. C. Yuen.

Part II.—P. C. Basu, Samuel Bradbury, Isabella M. G. Butler, T. V. L. Crichlow, James Grieve, K. H. Hallam, Elfrida L. G. Hilton, C. C. Kapila, Ethel E A. Pepper, H. W. A. Post, Raseela Rekhi, F. P. Schofield, and I. C. C. Tchaperoff (*Cai*).

Royal College of Surgeons of England.

Six Hunterian lectures on Human Monsters and Malformations, illustrated by specimens from the museum, will be given by Sir Arthur Keith on Mondays, Wednesdays, and Fridays from May 4th at 5 P.M. (except on May 15th, when the time will be 4 P.M.).—In two lectures on experimental research at the Pasteur Institute, Coonoor, South India, Colonel Robert McCarrison, I.M.S., will describe diseases induced in animals by faulty nutrition and discuss the causation of urinary calculus in man and in cattle in India. These lectures will be given at 5 P.M. on May 18th and 20th.

West-End Hospital for Nervous Diseases.

Speaking at the annual meeting last week, Sir Leonard Brassey said that this hospital has for many years had the largest neurological out-patient department in the country. The report states that of all types of hospital there is none more literally national in its sphere, patients having been received last year from 33 out of 52 counties, as well as from overseas. The expenditure exceeded the income by £1771.

Bayliss-Starling Memorial Scholarship.

This scholarship, founded in memory of Sir William Bayliss and Prof. E. H. Starling, is tenable at University College, London, and is of the annual value of about £120, with exemption from tuition fees. The scholar will be required to follow a course of study approved by the Jodrell professor of physiology, involving a training in the principles of, and methods of research in, physiology and biochemistry. Candidates must apply to the secretary of the College not later than May 15th.

Society of Apothecaries.

A Livery dinner was held in the Hall of the Society of Apothecaries on Tuesday, April 28th, when Col. C. T. Samman, the Master, presided, supported by the Wardens, Col. E. C. Freeman and Dr. Cecil Wall. Mr. Arthur Greenwood, Minister of Health, was the principal guest.

After the loyal toasts Sir Stanley Hewett, Surgeon Apothecary to the King, was awarded the honorary diploma of the Society, and in presenting the new licentiate to the Master, Sir William Willcox made an interesting résumé of the history of the Society which extends now over 300 years, and referred to the fact that throughout that long expanse of time only two honorary diplomas had been granted by the Society, the holders being the present Prince of Wales and Sir John Lynn-Thomas.

The toast of the Civil Service was proposed by Mr. Greenwood, who took occasion to point out to the audience how deep was the debt owed by the public to the faithful servants of the State, whose duty it was to remain constant in their ideals of service while through political necessity being under the rule of successive different Ministers. In the course of his speech he made special reference to the difficult position in which public servants are placed when personally attacked in the papers because they have no right to reply. Here he was speaking not only of private complaints but of the utterances of politicians holding office and other public representative men who used the medium of the newspapers to attack a body who are unable to reply from the nature of their offices. He claimed for the British Civil Service a high position as a body of men who were capable, reliable, and honourable, and who spent their lives in the public weal. The toast was replied to by Sr. Arthur Robinson, the Secretary to the Ministry of Health.

The toast of the guests was proposed by Sir George Makins, and Sir John Bland-Sutton, Lord Ebbisham, and Mr. Whiteley, K.C., replied.

Royal Berkshire Hospital.

An appeal is being made for £30,000 to liquidate the debt on the Blagraves branch hospital, and it is calculated that a contribution of two shillings per head from the population of the county would provide this money. An amount has therefore been apportioned to each parish, solely on a population basis, and each unit is being asked to aim at this "target."

Perth Mental Hospital.

James Murray's Royal Mental Hospital, Perth, has just been extended by the erection of the Gilgal Hospital for the treatment of patients suffering from mild nervous and mental breakdowns. The wards, each of which has its private veranda and garden, provide for 40 patients. The hospital contains a certain quantity of antique furniture, and most of the rest has been made locally to the design of Dr. W. D. Chambers, the physician-superintendent.

Extension of Dunfermline Hospital.

Last week Sir Ralph Anstruther, Lord Lieutenant of Fifeshire, opened the completed extensions to the Dunfermline and West Fife Hospital. The old part of the hospital has been completely renovated and re-equipped, and a large out-patient department added, at a cost of £10,000. The nurses' home at Priory House has also been enlarged and improved

The Booking of Out-patients.

The experiment of booking appointments for out-patients at the Manchester Jewish Hospital is reported to be a complete success. It is found that the doctors are never "held up" since any patient not in time loses his turn, and it is calculated that the patients' time is being saved at the rate of 200,000 hours a year. Inquiries as to the working of the scheme are being received from all parts of the world.

Excess of Out-patients.

Last year the patients admitted to the Norfolk and Norwich Hospital numbered 5973, an increase of 283 over the preceding year, and the largest on record. Their average stay was 19·4 days. The number of new out-patients—18,025—was fractionally smaller than in 1929. Attendances, however, increased from 87,572 to 93,029. The board of the hospital point out that the continued increase in the work of the out-patient department "is neither necessary nor desirable, as many of the patients now sent to the hospital could be effectively treated by their own medical attendants."

Memorial to William Smellie.

Last Saturday Prof. Munro Kerr unveiled the renovated memorial stone to Dr. William Smellie in St. Kentigern's Old Churchyard, Lanark. Dr. Haig Ferguson, President of the Royal College of Surgeons of Edinburgh, recalled that Smellie, who had been described as the greatest of British accoucheurs, died in 1763. Two years ago the Edinburgh and Glasgow Obstetrical Societies visited Lanark and agreed that it would be a fitting thing to renovate the tombstone as a tribute to the great man whose memory they desired to signalise and perpetuate. Prof. Munro Kerr related that Smellie was born in Lanark, was admitted a member of the Faculty of Physicians and Surgeons in Glasgow in 1733, and received the M.D. of Glasgow University in 1745. He had practised for 19 years in Lanark and then gone to London. Smellie was what would now be termed a great obstetric surgeon, and his case-records and writings could still be read with great interest and profit.

Rockefeller Medical Fellowships.

The Rockefeller Medical Fellowships for the academic year 1931–32 will shortly be awarded by the Medical Research Council, and applications should be lodged with *the Council not later than June 1st.* The Fellowships are provided from a fund with which the Council have been entrusted by the Foundation. Fellowships are awarded to graduates who have had some training in research work, in the primary sciences of medicine or in clinical medicine or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. In special circumstances the Fellowships may be tenable at centres of research not in America. A Fellowship held in America will have the value of not less than £350 a year for a single Fellow, with extra allowance for a married Fellow, payable monthly in advance. Travelling expenses and some other allowances will be paid in addition. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen-street, London, S.W.1.

Collections at Glasgow.

The Glasgow university students collected the sum no less than £15,070 for local charities on Jan. 17th of year, and this was allocated last week by the stud representative council executive. The recipients of the largest amounts were the Royal, Western and Vict *Infirmaries, which each received over £2000;* the Roy Maternity Hospital and Royal Hospital for Sick Chil both received slightly less.

A Florentine Hospital.

The Ospedale di Camerator on one of the slopes of the Fiesole hills, which has developed from the A Hospital for Italian Wounded erected during the wa was opened recently. After the war the original hosp became a free dispensary for the scattered population the Fiesole district, and later on a nursing home of ten was added. The new fully equipped hospital has men's women's, and children's wards and a few private wards f paying patients with a total of 50 beds. It has hi been difficult in Florence to obtain accommodation for and travelling foreigners with nurses speaking their ow language.

Appointments

HUME, J. BASIL, M.S. LOND., F.R.C.S. Eng., has been appointed Assistant Surgeon to St. Bartholomew's Hospital.

WILKINSON, K. D., M.D., Ch.B. Birm., Consulting Physician to the Nuneaton General Hospital.

Certifying Surgeons under the Factory and Workshop Acts: FRANKS, J., L.R.C.P. Lond., M.R.C.S. Eng. (Winchester); FOURACRE, S. F., M.B., B.S. Lond. (Withernsea, Yorks); MAXWELL, L. B., M.B., Ch.B. Camb. (Sutton, Surrey); MACPHAIL, A., M.B., Ch.B. Aberd. (Stornoway, Ross); OWEN, L. E., L.R.C.P. Lond., M.R.C.S., Clynderwen, Pembroke).

Vacancies

For further information refer to the advertisement columns.

Ashton-under-Lyne District Infirmary.—H.S. At rate of £150.

Barrow-in-Furness, County Borough.—Asst. M.O. £500.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. At rate of £100.

Birkenhead General Hospital.—H.P. £100.

Birmingham City Babies Hospital, Maternity and Child Welfare Dept.—Jun. Res. M.O. At rate of £100.

Birmingham, Dudley-road, Hospital.—Jun. Asst. M.O.'s. Each at rate of £200.

Birmingham General Hospital.—Two Res. Anæsthetists. Each £120. Also Two Res. H.S.'s. Each £70.

Birmingham Queen's Hospital.—Cas. H.S. £70. Also H.P. for Midland Nerve Hospital. £70.

Birmingham University.—Tutor in Dental Clinical Subjects. £800.

Birmingham University, Faculty of Medicine.—Chair of Anatomy. £1100.

Bradford Royal Infirmary. H.P. and H.S. Each £150.

Brentwood, Essex County Mental Hosp.—Jun. Asst. M.O. £510.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Cancer Hospital, Fulham-road, S.W.—Director of Research Inst.

Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.

Chesterfield and North Derbyshire Royal Hospital.—Cas. O. At rate of £200.

Cheyne Hospital for Children, Cheyne-walk, Chelsea, S.W.—Hon. Surgeon for Diseases of the Throat, Nose, and Ear.

Constance-road Institution, East Dulwich, S.E.—Asst. M.O. £350.

Croydon County Borough, Mayday-road Hospital—Res. Asst. M.O. £300.

Croydon, Mayday-road Hospital.—Res. Asst. M.O. £300.

East Ham County Borough.—Asst. M.O. £500.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. Cas. O. £125.

Gloucester, Gloucestershire Royal Infirmary.—2nd H.S. £120.

Great Yarmouth General Hospital.—H.S. £140.

Hackney Hospital, High-street, Homerton, E.—Temp. Asst M.O. At rate of £250.

Hellingly, East Sussex County Mental Hospital.—Two Jun. Asst. Res. M.O.'s. Each £350.

Hong-Kong University, Faculty of Medicine.—Professor of Pathology. £1000.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Asst. Physician. Also two Med. Regs. Each £200.

Hospital for Sick Children, Great Ormond-street, W.C.—Ophth. Surgeon.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W. Res. H.P. At rate of £100.

Hull Municipal Maternity Home and Infants Hospital.—Jun. Res. M.O. £100.

Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.

Ilford Borough.—Asst. M.O.H. £600.

Ilford, King George Hospital.—Two Hon. Anæsthetists. Each £50.

Kidderminster and District General Hospital.—H.S. £150.

Kingston-upon-Thames, Surrey County Mental Hospital.—Jun. Asst. M.O. £350.

Leeds General Infirmary.—H.S. to Radio Surg. Dept. At rate of £100.

Leeds Hospital for Women.—H.S. At rate of £50.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £100.

Leicestershire and Rutland Mental Hospital, Nasborough, near Leicester.—Asst. M.O. £350.

Liverpool Eye and Ear Infirmary.—H.S. to Ophth. Dept. £100.

Liverpool Hahnemann Hospital, Hope-street.—Res. M.O. At rate of £100. Also Clin. Asst.

London Jewish Hospital, Stepney Green, E.—Med. Reg. £100. Surg. Reg. and Ear, Nose and Throat Reg. Each 60 guineas. Res. M.O. and Cas. O. Each at rate of £150. Also Jun. Res. M.O. At rate of £100.

London Hospital, E.—Asst. Phys. to Children's Dept.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Middlesex County Council.—District M.O. and Public Vaccinator for Parish of Harefield. £45.

Mile End Hospital, Bancroft-road, Mile End, E.—Temp. Asst. M.O. At rate of £250.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Hon. Surg. to Orthopædic Dept.

Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £120.

Oldham Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.

Oxford Eye Hospital.—H.S., £150.

Plymouth, South Devon and East Cornwall Hospital.—Res. Surg. O. and H.S. At rate of £150 and £100 respectively.

Poplar Hospital for Accidents, East India Dock-road, E.—Sen. Res. O. £200.

Radium Institute, Riding House-street, W.—H.S. At rate of £150.

Rochester, St. Bartholomew's Hospital.—Res. Surg. O. At rate of £225.

Rotherham Hospital.—H.P. £180. Cas. H.S. £150.

Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. at rate of £150 and £100 respectively.

Royal Free Hospital, Gray's Inn-road, W.C.—Asst. M.O. for V.D. Dept. £350. Also Sen. Clin. Asst. for Infant Welfare Dept.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Alfege's Hospital, 48, Vanburgh-hill, Greenwich, S.E.—Temp. Asst. M.O. At rate of £250.

St. Andrew's Hospital, Bow, E.—Temp. Asst. M.O. At rate of £250.

St. Bartholomew's Hospital, E.C.—Asst. Physician-Accoucheur.

St. Giles' Hospital, Brunswick-square, S.E.—Temp. Asst. M.O. At rate of £250.

St. James's Hospital, Ouseley-road, Balham, S.W.—Temp. Asst. M.O. At rate of £250.

St. Mary Abbott's Hospital, Marloes-road, Kensington, W.—Asst. M.O. £350.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. At rate of £175.

Sheffield Royal Infirmary.—Vacancy in Hon. Surgical Staff.

Stalybridge Borough.—M.O.H. £850.

Swansea General and Eye Hospital.—Cas. O. £200.

Taunton, Taunton and Somerset Hospital.—H.P. £100.

University College, W.C.—Bayliss-Starling Memorial Scholarships. £120.

Walsall Manor Hospital.—Jun. Res. Asst. M.O. £150.

West Bromwich, Hallam Hospital.—Res. H.S. £250.

Wigan Infirmary.—H.S. At rate of £150.

Worksop, Victoria Hospital.—H.S. At rate of £170.

Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Dalston (Cumberland).

NOTES, COMMENTS, AND ABSTRACTS

4

MAINTENANCE OF TUBERCLE-FREE HERDS OF MILCH COWS.

TWENTY-FIVE years' experience in Birmingham has shown[1] something of the difficulties experienced in the maintenance of tubercle-free herds. Breeders everywhere will be grateful to the Hannah Dairy Research Institute for its bulletin on this subject just issued.[2]

In the autumn of 1923 there were 16 producers of Certified or Grade A (T.T.) milk in Scotland, and in 1928 their number had increased to over 90. Information was supplied to the investigators by the owners of 96 herds, comprising, at the spring test of 1929, 3913 cows, of which 53, or 1·35 per cent., reacted. During the whole inquiry 28,221 official tests were recorded, of which 428 were positive. This represents an average annual loss of three reactors per 100 head of milking stock. Ideally, after the initial clearing of the herd, the subsequent percentage of reactors should be reduced to nil. In practice only 18 out of the 96 herds investigated attained this ideal. Among these 18, there were six herds comprising respectively 76, 28, 103, 30, 40, and 27 animals, which have had no reactor for six years.

CAUSE OF FAILURE.

With the help of the owners and the county veterinary officers, investigation was made into the probable cause of failure in the case of 462 reactors. and the conclusion reached that failure was due in 34 per cent. to infected stock purchased, which was supposed to be tubercle-free; in 24·5 per cent. to contact with other reactors or untested stock; in 11·5 per cent. to infection from contaminated premises and pastures; in 19 per cent. to miscellaneous and multiple sources of infection; in 4·5 per cent. to anomalous tuberculin tests; and in 6 per cent. they were unable to trace the source of infection.

HOW TO ENSURE SUCCESS.

In order to eliminate the main sources of infection in tuberculin-tested herds it is recommended that during the initial stage of clearing the herd a three-monthly test be adopted in order to limit the period of contact between tubercle-free animals and infected stock. The authors strongly advise the adoption of a uniform technique and the use of a standardised tuberculin, and suggest the double intradermal test as being of outstanding merit. All doubtful cases, they say, should be classed as reactors. They strongly urge that the herd should be maintained by breeding only, tubercle-free bulls being used for service. When occasional purchases have to be made they should not be made in the open market, and the veterinary surgeon, who gives the clean certificate, should also supply the history of the animal and of the conditions on the farm from which it is purchased, and whether there has been any opportunity for contact with non-tested animals. Precautions should also be taken for the transit of the new purchase, which should be isolated after its arrival until two confirmatory official tests have been made three months and six months respectively after arrival. The authors also make the suggestion that an agency for facilitating safe purchases might be undertaken by the Scottish Certified and Grade A (T.T.) Milk Producers Association.

PRECAUTIONS ON THE FARM.

To prevent the spread of infection on the farm it is the following precautions are suggested: (1) Drastic disinfection after reactors have been discovered, and the temporary isolation of cows in adjoining stalls. (2) Protection of the tubercle-free herd from pastures liable to be contaminated with infected manure. (3) Double fencing from fields in which untested stock are likely to graze. (4) If cattle are exhibited at shows they must be protected during transit and have separate accommodation at the show from that occupied by untested stock.

If all these recommendations had been carried out, it is estimated that 90 per cent. of the 462 reactors in the present inquiry would not have contracted infection. Even as it is, the occurrence of 3 per cent. of reactors is a source of irritating expense to the owners rather than of danger to the consumer, for it is hardly possible for a reactor to have reached the dangerous stage in the period between two six-monthly tests. The latter point is specially emphasised in the preface to the Bulletin by Dr. T. Drummond Shiels, M.P., chairman of the Research Grants Committee of the Empire Marketing Board, and receives confirmation from the fact that during 1927 and 1928, when the Glasgow hospitals were supplied with milk from tuberculin-tested herds, of 550 samples examined not one sample was found to be infected.

POINTS TO BE CLEARED UP.

There are some points as to which further research is needed. In the very early stages of infection there is a pre-sensitive period during which the tuberculin test is inadequate to diagnose infection. This period may last for eight weeks or more, and explains a few cases where a purchased animal, certified as a non-reactor, may react at the subsequent test. There are also cases in which an animal reacts to tuberculin at an early test, subsequently passes similar tests for years, and ultimately breaks down perhaps under a severe strain such as difficult calving. This temporary loss of reactivity is explained by the incapsulation of an old lesion. It is therefore important to exclude all animals, which have ever reacted, from tubercle-free herds. If a general scheme for eradication were adopted, it would be necessary and quite reasonable to enforce the branding of all reactors.

The Hannah Research Institute has published a very valuable survey of existing knowledge on this subject. Perhaps the principal change since the last decade of the nineteenth century is the recognition that a short exposure is all that may be necessary for the passage of infection from one animal to another. For example, Nocard in 1893 (Les tuberculoses animales) wrote that transmission only takes place as the result of an intimate and prolonged cohabitation, and that the sojourn in a common pasture may be looked upon as free from danger. The bulletin makes no reference to the possibility of infection from tuberculous pigs or poultry.

EDUCATION AND ENTERTAINMENT FOR THE BLIND.

THE advantage of being able to read Braille is obvious to anyone who has imagined the state of blindness and its hardships. Instruction in this accomplishment is, of course, a fundamental part of work for the welfare of the blind and in cities it is a need which is met with fair success. In country districts, however, there may be only one instructor with a hundred or more charges in widely separat places. Often his visits are at intervals of over a month and between whiles the blind people easily forget their lessons and make little progress unless a relative or neighbour can give them frequent assist ance. This is not always easy, for the ordinary embossed lettering of Braille is by no means readily understood by would-be helpers, while reference to alphabetical lists and code books may make big demands on time and patience. With this in mind Dr. F. W. Alexander has set himself to construct key-boards which will simplify the task of the learner and also be a convenient guide to the amateur teacher. As at present constructed they consist of drawing boards on which the letters of the Braille alphabet are marked by round-headed nails. The signs of this alphabet, as is well known, are varying combinations of six points as on a domino, and on Dr. Alexander's board the sextet is always completed with small screws (nearly flush with the wood) so that the blind person can feel all six points and thus appreciate the relative positions of the Braille dots (round-headed nails). Against each Braille letter is its typewritten equivalent, for the benefit of sighted instructors, and the task of teaching is further simplified by the nail-heads being variously coloured according to whether the symbols are letters or word signs or abbreviations. These last are numerous in Braille, but a set of several boards will furnish the blind learner with all he needs, and will make it easy for anyone with sight to continue the work of an official instructor. Probably it will be found convenient to make the reference boards in other and cheaper materials, but some such "contraptions" (to use the inventor's word [1]) are likely to be of real service.

---

[2] Reactors in Tuberculin-Tested (Licensed Herds) by Alexander B. Fowler, B.Sc. (Agric.), and Norman C. Wright, M.A., Ph.D. Bulletin No. 2. Price 2s. post free from the Secretary of the Hannah Dairy Research Institute, Auchincruive, Ayr.

Having retired from the post of medical officer of health for Poplar, Dr. Alexander is now devoting his ingenuity to devising leisure occupations and games for the blind. He hopes to get amateur handicraft workers to help him in providing various kinds of puzzles, and he has shown us many samples which are well adapted to the amusement and interest of people who must rely on the sense of touch. The objective of many of them is to fit irregular flat pieces of wood or cardboard into geometrical figures, and for puzzles of this kind it is easy to supply a key consisting of similar pieces glued into position. It is surprising, however, to find how many other kinds of problem can be made to meet the requirements of the blind, and there are many games which they could play besides those already available to them. Dr. Alexander is to be congratulated on his well-directed efforts to fill a gap, and we hope he may find willing hands to carry out his plans.

MATERIALS OF BREAD-MAKING.

In this country the problem of the proper composition of bread is not now acute as it was during the late war when wheaten flour had to be eked out with other cereals. But in Italy even at the present day a shortage of wheat has necessitated its admixture, with rice in the Vercellese, with rye in the Alto Adige, with maize in some parts of Lombardy, and with potato flour in part of Calabria. History records, says Prof. V. Ducceschi,[2] that the Romans generally ate wheaten bread, but in Galen and Pliny reference is also made to barley, maize, and rye bread. This was probably due to the neglect of the cultivation of wheat and the great prevalence of inferior cereals. Towards the end of the Middle Ages, however, wheat culture resumed its importance, and this fact, together with the introduction of maize, diminished the use of other materials for bread-making, while the cultivation of the potato in 1800 also had an influence in this direction. Prof. Ducceschi gives tables showing the percentage of protein, fat, starch, cellulose, salt, and water in wheat and other cereals, including potato and chestnut flour and soya bean. He concludes that every addition, except soya and milk powder, tends to deprive bread of the nutritive properties which characterise the classical food made from wheat. Certain economic considerations also come into account, and in Italy even if rice, rye and potato added in certain proportion make a good bread, this fact does not entirely compensate for the deficiency of wheat. For example, rice which makes a good mixed bread might be exported to purchase a much larger quantity of wheat. Of the various types of mixed bread, maize-flour does not contain gluten, and is, therefore, not well suited for breadmaking as it does not leaven easily and the bread after baking has little substance and softness. It is, on the other hand, rich in fatty material and therefore predisposed to change, acquiring a disagreeable smell and taste. But the addition of maize-flour up to a proportion of 10–15 per cent. does not unfavourably influence the physiological and hygienic qualities of the product thus obtained. The admixture of potato-flour to the extent of 20 per cent. is one of the most advantageous from a technical and hygienic point of view, but from the point of view of national economy must be judged on its own merits, since it may be better for the people to eat potatoes in the usual manner than to use them as an addition to wheat flour. The admixture of rye gives a dirty colour to the bread and is not to be recommended when the proportion of this cereal exceeds 10 per cent., in any case it should not be more than 30 per cent. As regards rice, the offal produced by polishing would certainly add a certain nutritive value to bread as it is rich in proteins and vitamins; recently the admixture of 5 to 10 per cent. of rice has given satisfactory results in some parts of Italy.

Investigations by Prof. Ducceschi on feeding with wheaten bread mixed with 10 per cent. of soya have shown that it is equal to that of bread made of the best wheaten flour alone, and with 20 per cent. is only slightly inferior as regards absorption, and content in nitrogenous substances, fats, and carbohydrates, and when the soya is deprived of fat an admixture of 10 to 20 per cent. to wheat flour is utilised by the human organism to the same extent as white bread made with the best wheat flour alone. The soya bean would acquire a greater importance than it has at present if it could be profitably cultivated, as may happen in Italy and especially in her colonies.

Experiments at Milan have shown that the addition of 1 kg. of milk powder (corresponding to about 8·5 litres of fresh milk) to every quintal of flour will produce a bread more nutritious than the ordinary kind—porous, homogeneous, well leavened, of good keeping qualities, and tasteful. Since 1 kg. of milk flour costs 6 lire, the price of the bread would be increased to a negligible extent by the addition.

Prof. Ducceschi concludes his paper by remarking that when Italy is self-sustaining as regards food, which is an important factor in political safety, it will perhaps be possible to leave out of consideration the question of breadmaking with mixed flour; but meanwhile it is prudent to be prepared for any event.

HOMER'S SURGEONS.

[*To the Editor of* THE LANCET.

SIR,—I have read with great interest in THE LANCET Mr. Woods's article on the sons of Asklepios. The author does not mention Prof. O. Körner's new book on the medical knowledge in Homer (Die ärztlichen Kenntnisse in Ilias und Odysse, Munich, 1920). Speaking of Nestor's female slave Hekamede Mr. Woods declares her to be an apothecary, because she is said to know all the plants that grow on the earth, a statement which he thinks an exaggerated one. May I suggest that he makes here a confusion between Hekamede and Agamede, the widow of Mulius, whom Nestor had killed long ago in his youth so that she must have been a very old lady at the siege of Troy. Agamede is the Homeric form for Medea—hence her astounding knowledge of pharmacology.

I am, Sir, yours faithfully,

E. FULD.

Berlin, April 24th, 1931.

SALUBRIDAD.

THE bulletin of the Mexican department of public health is appearing in a new form under the direction of the Service of Propaganda and Hygienic Education. An interesting article in the first number deals with the terribly insanitary state of the holy water in Catholic churches where worshippers repeatedly put their fingers or hands into the basins, kiss the images, and press their faces against the walls of the confessionals. Some of them are obviously suffering from the skin diseases so common in Mexico and hope to get cured by touching the images. Another article by Dr. Saucedo y Andrade, chief of the sanitary delegation in Tepic, gives an account of a skin disease called *el pinto* (probably the same word as *pintojo*, mottled) endemic in some parts of Mexico among the mestizos or half-bred population. *Pinto blanco*, the commonest form, is clearly a form of vitiligo, but the description of other forms such as *pinto color* (with excess of pigment), *escamosis* (scaly), and *plomizo* (lead coloured) suggests that several diseases are included in the one name and require careful sifting. The prevalence of rabies in Mexico is shown by a review of the successful results of inoculation on the lines suggested by Semple; only two out of 540 persons treated developed rabies and they were late in coming for treatment. The advantage of this carbolised vaccine is that it preserves its potency and is easily transportable. The remainder of the volume is taken up with official reports. Prof. Hoffmann, head of the bureau for biological investigation, reports on the rôle of the sinulidæ in the dissemination of onchocercosis. The impression gained from a study of this volume is the colossal task confronting the Mexican department of health, and the unrivalled field offered to the scientific investigator in every branch of medical inquiry.

NEW PREPARATIONS.

"WELLCOME" BRAND DIPHTHERIA PROPHYLACTIC T.A.F.—Diphtheria Prophylactic (Toxoid-Antitoxin Floccules), designed to produce active immunity, is prepared at the Wellcome Physiological Research Laboratories. When toxoid and antitoxin are mixed, floccules are formed which retain the immunising power of the toxoid. Removal of the supernatant liquid allows 99 per cent. of the nitrogenous bodies present in the broth after growth of the bacilli to be discarded, with a resultant diminution of the tendency of the preparation to cause undesirable reactions. With the low liability to cause reactions the preparation shows unusually high immunising power. It is issued in bottles of 1 c.cm. and 10 c.cm.

DISPERT PRODUCTS (Messrs. Coates and Cooper, 41, Great Tower-street, London, E.C.), acting as distributing agents for the manufactures of the Krause Medico-Gesellschaft, are introducing to the medical profession three of their preparations obtained by the Krause process of drug isolation. The samples sent include Digitalis Dispert, Pancreas Dispert, and Valerian Dispert, and each preparation can be employed in the conditions in which the name suggests that it has been found useful, the dosage being scientifically regulated by careful standardisation. The firm state that to medical men interested they will send samples of the products and a description of the Krause process.

We have also received from Messrs. Coates and Cooper a sample of IDOZAN, a preparation of iron with a good history behind it, for it was placed on the market nine or ten years ago (THE LANCET, 1922, ii., 1283) by the firm of Charles Zimmermann and Co. It is now distributed by Messrs. Coates and Cooper.

BYNO-EUGASTROL (Messrs. Allen and Hanburys, Ltd., Bethnal Green, London, E.) is a concentrated extract of hog's stomach presented in a palatable and assimilable form, the antianæmic and blood regenerative principles of the gastric tissue being provided in combination with liquid malt. The preparation is made up in 4, 10, and 20 oz. bottles, and three tablespoonfuls represent an amount of extract equivalent to 100 g. of fresh stomach tissue. This is the usually recommended daily dose, though it will vary, of course, in accordance with the response of the patient and the directions of the medical man. As happens in the liver treatment of anæmia, the course may have to be indefinitely persevered in, but daily administration is not necessary after the anæmia has disappeared.

LACTOGEN (Nestlé and Anglo-Swiss Condensed Milk Co., 6 and 8, Eastcheap, London, E.C.), modified dried full cream milk, is supplied in ti which contain the equivalent of four pints of milk with milk-sugar added. The recommendations for infant feeding are set out in tabular form in accordance with the age of the infant, and the warning is appended to the table that dilutions do not necessarily produce fluids of the equivalent composition of normal milk. Lactogen, though designed mainly as an infant food is also recommended as a properly constituted diet for invalids and convalescents, the manufacturers claiming that it is not merely a dried milk powder but that it is specially prepared to obtain proper physiological balance. Thus the addition of carbohydrate to the cream enriched fresh milk corrects a natural deficiency, while reducing the excess of protein. The addition of fresh fruit or vegetable juice is recommended, as supplying a needed accessory food factor.

NEOTROPIN (Messrs. Schering, Ltd., 3, Lloy avenue, London, E.C.) is a urinary antiseptic for administration, its chemical composition b butyl oxydiamino-azo-pyridin. The manufactu supply details of the procedure they have ad for testing the bacteriological efficacy of the and state that its use has proved considerable disinfectant of the urinary tract prior to su interference or in the post-operative treatment of surgical cases and in gonorrhœal affections.

BOTOL (Continental Laboratories, Ltd., 3 Marsham-street, London, S.W.).—This p consists of bromoform combined with codeine aconite, and belladonna, and is recommended pertussis and spasmodic or convulsive coughs. T preparation is supplied in tablet form, and should not be employed save under medical directions, but in suitable cases would be valuable.

Births, Marriages, and Deaths

BIRTHS.

BATTERSBY.—On April 18th, the wife of F. J. G. Battersby, of The Tower House, Malmesbury, Wilts., of a son.

LINDUP.—On April 15th, at Floriana Malta, the wife of Flight Lieut. C. A. Lindup, R.A.F. Medical Service, of a daughter.

MILLOY.—On April 23rd, at Wilbraham-place, S.W., the wife of John M. Milloy, M.B., F.R.C.S., of a son.

SEWARD.—On April 24th, at Southerhay West, Exeter, the wife of Charles Seward, M.D., M.R.C.P., of a daughter.

URWICK.—On April 21st, at Park-street, W., to Violet, wife of Dr. Desmond Urwick—a daughter.

MARRIAGES.

GOODWIN—CLAYTON.—On April 24th, at St. Mark's Church, Hamilton-terrace, N.W., Aubrey Goodwin, O.B.E., M.D., F.R.C.S., to Hilary, youngest daughter of Mr. and Mrs. C.E.H. Clayton, of Ruislip.

MARSHALL—BROWNE.—On April 23rd, at St. Saviour's Church, Warwick-avenue, W., Charles Wallace Marshall, M.D., to Helen Marion ("Gipsy") Browne, M.B., B.S.

DEATHS.

BEGG.—On April 21st, Charles Begg, M.B., C.M. (Edin.), in his 80th year.

BRAMWELL.—On April 27th, at Heriot-row, Edinburgh, Sir Byrom Bramwell, M.D., LL.D., D.C.L., in his 84th year.

KAY.—On April 22nd, suddenly, in London, Walter Smith Kay, M.D., of Harrogate, late Medical Superintendent of West Riding Mental Hospital, Wadsley, Sheffield.

TYRRELL.—On April 21st, in a nursing home, Walter Tyrrell, M.R.C.S., L.R.C.P., of Kensington Court-gardens.

WELSFORD.—On April 20th, in Rome, Arthur Gerald Welsford, M.D., F.R.C.S., aged 66.

YOUNG.—On April 25th, at King's College Hospital, after an operation, Colonel James Young, M.D., T.D., D.L., aged 6

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

THE SPLEEN: ITS STRUCTURE, FUNCTIONS, AND DISEASES.*

BY J. W. McNEE, D.S.O., M.D., D.Sc. GLASG.,
F.R.C.P. LOND.,
ASSOCIATE PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON.

LECTURE II.

I PROPOSE to describe first of all in this lecture the ore recent work on the functions of the spleen.

Functions of the Spleen.

CONTRACTILE POWER.

Contraction is the first and perhaps the most aportant function of the organ. The idea of splenic elaxation and active muscular contraction is not ew; it occurred to Stukeley (1722), and is clearly t forth in his Goulstonian lecture. Gray (1854) elieved the organ had a more passive rôle as a fety-valve for the portal blood, since his experi-ents, of which many were done on spleens freshly moved from the animal body, did not prove to m any active contraction. Roy (1881) was really e first physiologist specifically to investigate the ythmic movements and contractility of the spleen iring life, and his work was continued by Schäfer d Moore (1896). The results of the latter authors owed that the power of contraction of the spleen inherent in it, and may occur quite independently the nervous system. They also found that the olume of the spleen responds rapidly to alterations blood pressure, local and general, and that during phyxia general contraction and increased rhythmic ovement both ensue, but only so long as nerve ntrol is maintained. These last observations are much interest in view of Binet's more recent work, hich I shall describe presently. Stukeley's old iew of the spleen contracting as a pump was there-re gradually returning, and Mall (1900) states:—

> "I have found that in certain cases the pressure in the lenic vein may exceed the arterial, a condition which can brought about only in case the spleen contraction acts a pump. In one case the pressure in this vein rose to 0 mm. Hg, with the artery closed—i.e., the arterial essure practically at zero."

Study of the contractile power of the spleen there-ter remained in abeyance until about 1923–24, hen Barcroft and his colleagues in Cambridge began eir important series of observations. Barcroft's ork is now so well known that it is unnecessary to ve his methods in full detail, but it is interesting see how his research started. In an expedition to eru with a number of colleagues, to study the effects man of high altitudes, Barcroft was puzzled, even the voyage out, to account for the number of red rpuscles suddenly added to the blood as soon as ot weather was reached, and he was naturally also terested in the same phenomenon as it occurred high altitudes. Whence came this new blood tering the circulation quite suddenly? Obviously ly from some storehouse or reservoir where it ready lay available, and it was natural to think, had Stukeley before him, of the spleen. By a ries of ingenious experiments, and particularly by method in which a dog's spleen is brought out through a slit in the abdominal wall, and left active in situ, protected by saline dressings for weeks or months, he was able to show that the dog's spleen contracts actively under a variety of circumstances, such as exercise, heat, emotion. His experiments with carbon monoxide poisoning, already referred to, also showed conclusively the sudden emptying of the spleen-pulp during exercise. It may be remembered that the dog's spleen contains abundant muscle-fibre in its capsule, and contraction may be more definite in dogs than in other animals (and in man) in which the capsule contains elastic fibres only.

Binet and his colleagues in Paris (1926 onwards) have approached the same problem from a different angle. They had noticed, in experiments on animals with asphyxiating gases, a sudden rapid increase in the count of red corpuscles, which at first they could not explain. The increase is very rapid, and the blood count of an asphyxiated dog may rise 1,000,000 or even 2,000,000 per c.mm. within five minutes. Binet soon found that in animals from which the spleen had previously been removed, this increase in the blood count after asphyxiation failed to occur. A simulation of the effects of high altitudes (6000 metres) was also arranged in an experimental chamber, and here again precisely the same effects were noticed in the two classes of animals.

Thus the importance of the contractile power of the spleen as an ancillary respiratory organ, because of its powers of suddenly supplying additional oxygen carriers, appears to be amply proved.

Active contraction of the spleen has also been found to occur regularly after hæmorrhage, but Barcroft and his colleagues have shown that this contraction is most important and pronounced after a single experimental bleeding, and not when blood-loss is repeated. Thus the spleen, following a single hæmorrhage, may in a measure be regarded as an organ of auto-transfusion.

From all this important work on splenic contraction the following thesis emerges, which is well put by Barcroft in these words: "Were the organism presented with an issue which made its life depend on the amount of hæmoglobin it could produce, a splenectomised animal should die when an animal possessed of a spleen should survive." The correctness of this thesis was proved to the hilt by Barcroft in the following experiments. In animals poisoned with coal gas (carbon monoxide) splenectomised animals always die first, whereas in animals poisoned with hydrocyanic acid, in which the hæmoglobin is not involved, both normal and splenectomised animals die together.

While I cannot fail to be deeply impressed with the importance of the spleen as a ready and available source of red-blood corpuscles for sudden needs of the organism, I believe that the importance of the bone-marrow as an additional rapid supply of red corpuscles must not be lost sight of, especially after hæmorrhage. No one has suggested that the bone-marrow can act as a pump, and supply blood-cells by its contraction, but it seems evident from all our studies of the normal bone-marrow (quite apart from blood diseases in which the marrow is hyperplastic) that a large supply of red corpuscles is immediately available for any demand. This is shown by the appearance of the rapid post-hæmorrhagic leucocytosis, and by the presence of immature red corpuscles (normoblasts) in the blood very soon after a hæmorrhage. It seems possible that the supply from the bone-marrow is not so immediately available as that from the spleen, but none the less there must be in the normal bone-marrow a large store of ripe or nearly ripe red blood corpuscles which can be drawn into the general circulation at great speed.

---

* The Lettsomian lectures delivered before the Medical Society London on Feb. 16th and 25th, and March 4th, 1931. Lect. I. peared last week.

The actual *mechanism of splenic contraction and relaxation* is of great interest. The older work of Roy, and of Schäfer, and Moore has already been referred to, but Binet and his colleagues in Paris have reinvestigated the problems involved by greatly improved methods. The problem narrows itself down essentially to questions of enzyme action, nerve control, or a combination of both. In view of the fact that the spleen is known to change its volume definitely during digestion, secretin has been considered as the possible enzyme involved. On the experimental evidence, however, secretin as an exciting cause of splenic contraction must be set aside, although in France this enzyme is now believed to have an important influence on the recently described cholesterogenic function of the spleen (Binet, Abelous and Soula), which is referred to later on.

By laborious experiments with a crossed circulation in two dogs, the head of one animal being transfused with the blood of another, Binet concludes that there is a centre for splenic contraction in the medulla, which acts by the stimulus of asphyxia or of changes in blood pressure. Obviously, as Binet admits freely, this central nervous mechanism is very complex, and far from being completely understood; the centre may indeed possibly be the ordinary vasomotor centre.

A second mechanism by which the spleen is made to contract is completely proved—namely, by the liberation of adrenalin into the blood. It is probably this mechanism which comes into play in exercise and emotion.

Thus, so far as our knowledge has gone, the spleen may contract both by enzyme action (adrenalin) and by the influence of central nervous control.

BLOOD FORMATION.

It is now generally accepted that in fœtal life the spleen, together with the liver, actually manufactures blood corpuscles of every variety, both erythrocytes and leucocytes. In post-uterine life a reversion to this fœtal function occurs in a variety of diseases of the blood, a good example being von Jaksch anæmia. This so-called myeloid metaplasia has been systematically studied by Naegeli and many others in human diseases, and also in experimental anæmias. Lymphocytes are believed to be supplied to the blood by the Malpighian bodies throughout life, but we have still much to learn concerning the physiology of the lymphatic tissues. Following splenectomy in most normal animals a definite anæmia supervenes, which has been fully described by Pearce, Krumbhaar, and Frazier (1918) in "The Spleen and Anæmia." The cause of this long persisting anæmia is not yet understood, but it is obviously an important fact to remember after the operation of splenectomy on our patients. Experiments on animals suggest that the anæmia is due to loss of some stimulating effect of the spleen on the bone-marrow, all the evidence being in favour of a diminished production rather than an increased destruction of blood. No immature cells are found in the circulating blood, and Krumbhaar and his colleagues have shown that in animals the anæmia can be rapidly improved by the injection of splenic extracts.

DESTRUCTION OF BLOOD AND PRODUCTION OF BILE-PIGMENT.

Blood destruction and the production of bile-pigment are so closely related that they may conveniently be considered together. The fact that red corpuscles are destroyed by phagocytic cells of the spleen-pulp, in health in some animals and in disease in man, owed its earliest recognition to Kölliker and Ponfick. We believe nowadays that this function of intracellular blood destruction is a function of the reticulo-endothelial system of cells, of which the spleen is an important centre, but not by any means the only one. It is also now believed that in this intracellular process of destruction of red blood-cells the iron-free part of the hæmoglobin molecule is released into the blood stream as bile-pigment, to be ultimately carried to the liver for excretion by the hepatic glandular cells. The question of bile-pigment metabolism is a large one, which I have dealt with very fully elsewhere (McNee, 1923).

BLOOD-PLATELETS.

The relation of the spleen to blood-platelet production and destruction, and consequently to blood coagulation, are matters of very considerable importance from the practical point of view, and it is unfortunate that our information about them is so meagre. The problem first attracted attention after the cure, by splenectomy, of severe cases of purpura associated with very low blood-platelet counts. The marked rise in the platelet count following operation in these cases suggests that the spleen may either destroy blood-platelets or influence their production in the bone-marrow, but we are entirely without information on this subject. The further importance of blood-platelets in patients about to be operated on for other splenic diseases emerges from the work of Rosenthal and Howel Evans, but this is referred to again in detail later.

DIGESTION.

It has been thought from the earliest times that the spleen was in some way related to the digestive processes, and indeed it was suggested in primitive medicine that the spleen "warmed the stomach." Later, even in the seventeenth century, alterations in nutrition and in appetite were described in splenectomised animals. The problems involved are very difficult, but, without going into details, it may be said that most recent studies have shown that the ordinary metabolic processes of digestion are in no way changed in animals after splenectomy. The question of fat metabolism has been particularly investigated, but Krumbhaar and Musser were unable to demonstrate any disturbance in the fat metabolism of spleenless dogs. It has been known for some time (MacAdam and Shiskin, 1922–23) that the cholesterol content of the plasma is reduced in both pernicious and secondary anæmias, but rapidly increases again in these diseases after splenectomy. Abelous and Soula have claimed, on the other hand, that the spleen has a definite cholesterogenic function in the body. They arrived at this conclusion while engaged in work with secretin. They noticed, for example, that when 100 c.cm. of 0·05 per cent. HCl is inserted into the duodenum of a normal dog the cholesterol in the carotid artery blood may rise from 1·153 to 2·307 g. per cent. This increase does not occur in splenectomised animals. It is impossible to reconcile these opposing results of MacAdam and Shiskin and Abelous and Soula, but it may simply be said that the problems of the relations of the spleen to digestion and particularly to fat metabolism urgently need complete reinvestigation. There are good clinical reasons for such a suggestion, as the results might possibly explain the peculiar metabolic disturbances of the reticulo-endothelial cells in Gaucher's disease and hypercholesterolæmic splenomegaly.

IMMUNITY.

There is some exact knowledge about the relation of the spleen to immunity, and many statements that are purely conjectural. It is well known, for example, that the spleen, liver, and lungs are the chief places in which micro-organisms circulating in the blood are arrested and destroyed. This is shown clinically in the spleen by the acute enlargement characteristic of many fevers, such as typhoid and infective endocarditis. At first these facts seemed in no way connected with the question of immunity, but with the development of knowledge concerning antibody formation and especially with the development of the conception of the reticulo-endothelial system and its cellular reactions in infective diseases, the question of the spleen's place in the processes of immunity in general and in antibody production in particular, has attracted renewed attention. Luckhardt and Becht (1911) showed that in splenectomised dogs hæmolysins, hæmoagglutinins, and hæmopsonins are not produced so rapidly or in such good concentration as in controls. Morris and Bullock (1919) in rats infected with rat-plague bacilli proved that in splenectomised animals the mortality was far higher than in controls. There is some evidence that in tuberculosis removal of the spleen increases resistance to infection (Lewis and Margot, 1914–15), but, on the other hand, Morton has provided us with a rapid method for the diagnosis of experimental tuberculosis in guinea-pigs by irradiation of the whole animal, which must certainly injure the reticulo-endothelial cells in the spleen and elsewhere.

Much work has recently been done on so-called "blockade" of the reticulo-endothelium by Indian ink and other methods, and the immunity response of such animals has been tested in comparison with controls. There is now practically a consensus of opinion that a real physiological blockade is impossible for any length of time, and so the many experiments which have been done lose force. On the whole it seems probable that the reticulo-endothelial system of cells are in some way connected with the processes of immunity to infection, and so the spleen, as the chief source of these cells, must be regarded as important.

An important clinical point emerges from this discussion on immunity—namely, whether infective diseases are commoner or are poorly resisted in splenless individuals. A case reported by O'Donnell (1929), and commented upon by Parkes Weber (1929), is of interest. The patient, a boy, died some time after splenectomy of an acute fulminating infection thought to be purpuric meningococcal septicæmia. It is very desirable that all such cases should be reported in the literature for the information of those interested in the subject. I may add that in none of my fairly large group of cases, in which splenectomy has been performed, has there been any evidence so far of lowered resistance to microbic infection.

TUMOUR FORMATION.

It is a well known clinical fact that malignant tumours, both primary and metastatic, are of unusual rarity in the spleen. Murphy (1914), inoculating chick embryo tissue with grafts of rat sarcoma, found that when the graft was accompanied by a fragment of kidney it survived and the two grew readily together, but that when spleen tissue was substituted for kidney the graft died. Lazarus-Barlow and Parry (1923) also found that the spleen offers more resistance to grafts of Jensen's rat sarcoma than does any other organ of the body. Thus both clinically and experimentally the spleen seems to offer resistance to tumour growth, and there must be some good reason for this if we could find it.

In my own experience malignant tumour growth has occurred in two patients on whom splenectomy had previously been performed. In the first of these, a woman of 28 years at the time of operation, carcinoma of the tongue developed three years later. In the second case, a woman of 34 years, carcinoma of the pharynx caused her death three and a half years later. It would be interesting to know how many cases of this kind could be collected.

Classification of Diseases of the Spleen.

In a previous paper (1929) I gave a preliminary account of the pathology of over 100 spleens, all of them belonging to the group which I then preferred to call "splenomegalies of unknown or uncertain origin." Since then my collection has greatly increased, and I have had more opportunities for clinical examination of patients, and histological examination of specimens obtained either by splenectomy or, in some cases, at necropsy.

At the time when my first paper was written I attempted, on the pathological evidence then available, to give a rough and entirely tentative classification of the splenomegalies of unknown or uncertain origin. It would have been better had I avoided the word classification, since all I was really able to attempt at the time was a grouping or "pigeonholing" of the spleens examined according to their chief histological characters.

TENTATIVE GROUPING—1929.

1. Splenomegaly with peri-ellipsoidal hæmorrhages and nodular siderosis (? splenic mycosis).
2. Chronic hæmolytic (acholuric) jaundice.
3. Thrombo-phlebitic splenomegaly.
4. Chronic splenic hypertrophy, with or without fibrosis.
5. Banti's disease. Rare.
6. "Reticulo-endotheliosis" of the spleen. (*a*) Slight (? chronic infections), or marked; (*b*) lipoidal group—diabetes, &c.; (*c*) Gaucher-Pick-Niemann group. (*d*) tumours.
7. Undetermined group: (?) chronic aleukæmic leukæmia; (?) primary lymphadenoma of spleen and others.

I did not mean this grouping to be considered as indicative of actual disease-entities. It may be noted, for instance, that the first group was termed "splenomegaly with peri-ellipsoidal hæmorrhages and nodular siderosis." This very interesting lesion (believed by some writers to be due to mycotic infection) occurs, as is now becoming well known and as indeed I stated in my paper, in a number of entirely different varieties of splenomegaly or splenic disease. It therefore cannot form the basis of anything more than a tentative histological grouping, since it seems possible that the cause of these siderotic nodules must be the same in whatever type of splenic disease they may be found.

In the past few years I have also had the opportunity of examining a number of other, and somewhat rarer, examples of splenic disease, and I now wish to attempt a wider and more generally applicable classification of all splenic diseases. My classification must be based on pathology, since we are still a long way from accurate differentiation of these diseases by clinical means. As I have stated before, enlarged spleens removed by the surgeon from patients with apparently identical clinical histories may yet be very different in histological structure.

A classification of this kind can take no note of two terms which stand out prominently in clinical literature—splenic anæmia and Banti's disease—although the use of these terms may well be inevitable in ordinary clinical use for some considerable time. A full account of the history of these terms has been given by Rolleston (1914). "Splenic anæmia" was first referred to in medical literature by Gretsel (1866), but there is no doubt that two papers by Osler, in 1900 and 1902, were the means of making the term familiar to clinicians in America and in Britain. The description "Banti's disease" came into use after the papers by this Italian author, who several times elaborated his views in the Italian, French, and German literature, and thus ensured them prominence. Osler, in a discussion on nomenclature, affirms that "Banti's disease is simply chronic splenic anæmia *plus* features of cirrhosis of the liver, which represents a terminal stage in the disease. Banti's merit consists in calling attention to this important aspect, but, after all, these secondary changes in the liver are somewhat rare, and, as my records show, the hæmorrhages, ascites, and even the jaundice may be present without existing cirrhosis."

The general classification of splenic diseases, which I hope may be useful for ordinary working purposes, is chiefly based on a differentiation of histological changes as they affect one or other of the different essential structural parts of the human spleen. Abnormalities, tumours, and specific infections fall readily into their own special groups. The chief constituent structures of the spleen are: (1) the myeloid and lymphatic elements; (2) the endothelial elements (reticulo-endothelial system); (3) the vascular system, with its special peculiarities; (4) the reticulum and supporting structures of the spleen—capsule, trabeculæ, &c.

No classification of this kind can be perfect or in absolute watertight compartments, and it may simply be mentioned as an example of this that inflammation of the capsule (perisplenitis) and chronic inflammation of the supporting tissues (chronic splenic fibrosis) are common to many splenic diseases. I am unable to affirm at present that chronic inflammation of the reticulum (a structure possibly composed of elements different from white fibrous tissue) is a precursor of, or takes part in, the phenomena of ordinary diffuse splenic fibrosis, but I strongly suspect this to be the case. Fibrotic thickening of the fibro-muscular trabeculæ is easily understood.

Here, then, is the general classification of splenic diseases which I propose:—

GENERAL CLASSIFICATION OF DISEASES OF THE SPLEEN.

1. Abnormalities: congenital and acquired.
2. Infections: acute; granulomatous; parasitic.
3. Diseases affecting the myeloid and lymphatic elements.
4. Diseases affecting the reticulo-endothelial elements.
5. Diseases affecting the vascular system.
6. Tumours: simple; malignant (primary and metastatic).
7. Combined diseases of the spleen, liver, and hæmopoietic system (Eppinger's "hepato-lienalen Erkrankungen"), and splenic enlargement in hepatic cirrhosis.

Some explanation is required for the inclusion of the last group, and it is impossible for me to consider the problems involved with any degree of clearness combined with brevity. It may be sufficient to say that Eppinger's well-known book, "Die hepato-lienalen Erkrankungen" (1920) runs to more than 560 closely printed pages. In general this group includes diseases in which there are obvious inter-relationships between liver, spleen, and bone-marrow, and seeks for some explanation of why hepatic cirrhosis and particular forms of splenomegaly are so often combined to form a characteristic clinical syndrome. This group of cases interests me very greatly, but in the present lectures brevity compels me to do little more than refer to them so as to bring them into line.

It is well known that the spleen is enlarged in the majority of cases of hepatic cirrhosis; as a rule the enlargement is not great, but in some instances the spleen may be enormous. In the latter cases, however, we are faced with extreme clinical difficulties, and even in the post-mortem room it may be impossible to solve the problem of whether the case should be regarded as primary hepatic cirrhosis and secondary splenomegaly, or the opposite.

In the ordinary moderate splenic enlargement of portal hepatic cirrhosis there seems little need to invoke more than the mechanical effects of portal back pressure in most cases, but the toxæmic view, in which it is held that both liver and spleen have been equally damaged by the same poison circulating in the portal blood, has had many adherents. The whole question of splenic enlargement in hepatic cirrhosis is fully discussed in the book on "Diseases of the Liver," by Sir Humphry Rolleston and myself (1929).

Diseases of the Spleen.

I now propose to describe in detail some of the chief diseases of the spleen met with in this country, and which I have seen myself. It is obviously impossible within the limits of these lectures to deal with *all* splenic diseases, and I must therefore omit or merely refer to a number of diseases of which I have so far no personal records, and others in which the spleen is involved only incidentally as part of some general disease. Examples of the latter are the leukæmias, Hodgkin's disease, and syphilis. I shall also leave out all direct reference to tropical diseases of the spleen, although it would be very interesting to see how they would arrange themselves in the classification proposed for splenic diseases in Britain.

For the above reasons this section is bound to appear somewhat ill-balanced, since important diseases in which the spleen is involved must be passed over almost in a word. But information about these diseases is readily available, and I have thought it best to devote most of my time to clinical and pathological conditions which are either specially interesting or difficult to interpret.

ABNORMALITIES—CONGENITAL AND ACQUIRED.

Malformations and lack of normal development are, on the whole, of little practical interest. The spleen may be completely absent, or very many small spleniculi may be found scattered through the upper abdominal cavity. A point worth mentioning, not for its immediate practical importance but for its bearing on other pathological changes, and for its confirmation of what I have already described as an essential fact in splenic structure, is *congenital lobularity* of the human spleen. Division of the organ into five to seven separate lobes has frequently been recorded (Litten), and incomplete lobulation, indicated by deep indentations on the surface, is not uncommon.

FLOATING SPLEEN.

Floating spleen, or dislocation of the spleen, is a well-known acquired abnormality, of definite importance in abdominal diagnosis. It is found, as would be expected, far more often in females than in males, and although it is true that the majority of floating spleens are enlarged spleens, this is not always so. A floating or wandering spleen is ultimately, in almost all cases, affected by perisplenitis or inflammation of the capsule, and then may fix itself permanently in almost any part of the abdominal cavity, even in the hollow of the pelvis. Prior to its fixation, twisting of the pedicle may ensue. If the twisting is sudden, symptoms and signs similar to those produced by the twisted pedicle of an ovarian cyst may be present, but on the other hand less sudden twisting may lead to splenic atrophy without further trouble. The clinical diagnosis of floating or dislocated spleen may be quite simple or excessively difficult. One case seen by me closely simulated a large pyloric tumour and was tender on palpation; ultimately, audible friction was heard over the tumour, which strongly suggested the correct diagnosis. In another case, in a male, seen quite recently, a diagnosis of wandering spleen was made at first because of great mobility of the tumour (which could be pushed up below the ribs) and a suggestion of a definite notch. X ray examination, however, strongly suggested the presence of carcinoma of the stomach, and a test-meal showed absence of free hydrochloric acid. At operation a large somewhat horseshoe shaped carcinoma was found involving the posterior wall of the stomach, not adherent to any adjacent structures, so that a partial gastrectomy was easily carried out.

PERISPLENITIS.

This is a convenient place to consider a very common complication of many splenic diseases—namely, perisplenitis. Inflammation of the capsule may follow injury by a blow, and is the common method of fixation of a wandering spleen, but in practical medicine it is chiefly of importance in splenic enlargements due to disease. There is no doubt that the presence of even well-marked acute perisplenitis is often overlooked, since pain may be slight or absent altogether, and the physician is often unaccustomed to applying his stethoscope over an abdominal tumour. Occasionally the friction is so rough that it may readily be detected by the hand placed on the abdominal wall.

In one case seen by me, which ultimately proved to be one of primary sarcoma of the spleen, the patient sustained a fall from his horse. A friction sound was heard on the left side, which was thought to be due to pleurisy from injury or fracture of the ribs. It was only some time later that the spleen was found to be considerably enlarged, but it now seems certain, in view of the dense adhesions subsequently found to exist, that the friction sound was due to perisplenitis and not to pleurisy.

It is a fact, however, and an important one for the surgeon, that perisplenitis producing the loudest rubbing sounds, and recurring for months, need not necessarily lead to permanent adhesions between the spleen and the abdominal wall. The adhesions when soft may evidently be, so to speak, polished off by the rubbing, leaving the affected area covered with a dense polished milky coating.

In one patient, a girl aged 10, an enlarged spleen offered great difficulties in diagnosis, since the blood count and blood picture were perfectly normal. Repeated attacks of perisplenitis in this active child led me to advise splenectomy before the operation became a graver risk from adhesions. Actually the spleen was removed without difficulty, the capsule being greatly thickened but well polished and the adhesions easily separated. This case is referred to again later.

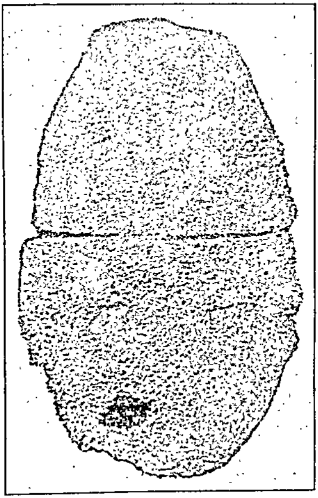
It is retrosplenic adhesions, and adhesions to the diaphragm, which are of far greater concern to the surgeon, since abundant vascular connexions are established which may give rise to oozing in deep places extremely difficult to control.

INFARCTION OF THE SPLEEN.

There is little need to do more than mention the extreme frequency of infarctions—both aseptic and septic, and varying greatly in size—in a number of diseases. The common occurrence of infarction is explained by our knowledge of the splenic vascular system, each of the main branches of the splenic artery being an end-artery in the truest sense, and supplying a potential splenic lobe. Each of the finer branches, moreover, supplies a potential lobule.

Total infarction of the spleen is rare, but may follow twisting of the pedicle of a wandering spleen.

FIG. 7.



Complete infarction of the spleen. (This specimen is now in the pathological museum of University College Hospital.)

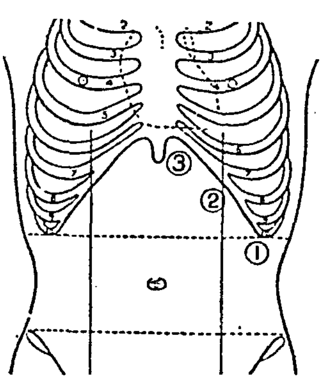
I have also seen a case of complete infarction, due to embolism of the splenic artery in a woman who had suffered from mitral stenosis and cardiac failure. The condition was only discovered at necropsy, and was not suspected during life.

The rarity of total splenic infarction, and the mechanism by which it may come about, has attracted the attention of Warthin (1901, 1907), Troell (1916), Richey (1918), and others, all of whom point out that in a normal animal ligature of the main artery does not result in infarction, but simply in gradual atrophy. The normal spleen apparently escapes necrosis because, although the branches of the vessel within the organs are true end-arteries, there are arterial anastomoses close to the hilum. Some additional factor such as disease of the spleen itself or definite abnormality in distribution of the blood-vessels must be present in order that blockage of the splenic artery should cause complete necrosis.

SPLENIC ENLARGEMENT IN FEVERS.

It is unnecessary to enter into any questions of pathology, since these are described in most textbooks. I shall confine myself to some simple clinical points in connexion with the diagnosis of early splenic enlargement. First, palpation of the tip of a slightly enlarged spleen is much easier in a broad-chested individual than in a patient with a narrow chest and acute costal angle, a point which I noted frequently when examining cases of trench fever during the later period of the war. I have, for example, examined a group of men from one platoon who fell ill together and were almost certainly infected about the same time. In the broad-chested men the spleen might be palpable, but not in the others. Secondly, it must be remembered that there are three places (see Fig. 8) where the hand should be placed to feel for a slightly enlarged spleen, and all three should be tried in turn before it is concluded that the spleen is of normal size. This point to some extent depends on the configuration of the individual, but also on the shape of the spleen itself.

FIG. 8.



TUBERCULOSIS, SYPHILIS, AND HODGKIN'S DISEASE.

I am unable to do more than mention the splenic enlargement in these three diseases. The matter is important chiefly in diagnosis, since apart from the spleen sharing the more generalised infection, massive tuberculosis of the spleen, or gumma, or what is believed to be primary invasion of the spleen by Hodgkin's disease, may all lead to considerable difficulty in the correct interpretation of a clinical case of splenomegaly.

SIMPLE HYPERTROPHY.

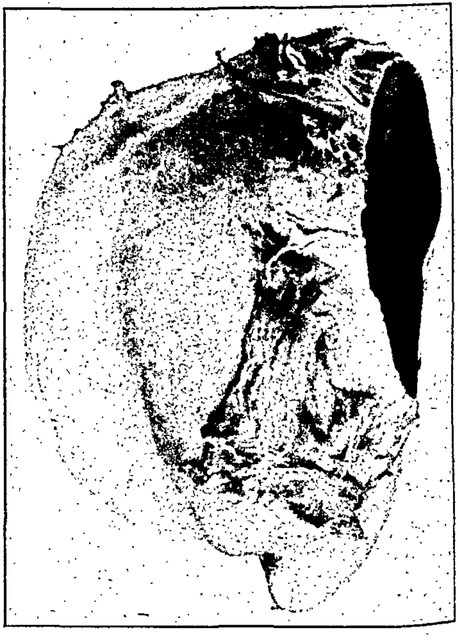
The size of the normal spleen varies considerably with age, as we have seen, but the cases I have in mind present themselves as definite splenomegalies associated with a secondary anæmia. Parkes Weber has suggested the descriptive term hypersplenism. In a patient of this kind, a young woman of 28 years, splenectomy was performed on a diagnosis of splenic anæmia. The spleen was considerably enlarged, but free from adhesions, and on histological examination I was unable to detect any abnormality whatever in its structure. I regard this case as one of pure splenic over-activity, resulting in anæmia. It was this patient who was readmitted to hospital three years later suffering from a large cancerous growth of the tongue.

CYSTS.

Three types of cysts in the spleen have been described: (1) dermoid, (2) echinococcus (hydatid), and (3) serous or hæmorrhagic. The two first mentioned are rarities, and I have not seen examples of either of them. Serous and hæmorrhagic cysts are the most important, especially in diagnosis and treatment. Small multiple serous cysts occur, but are of little practical importance and are generally found accidentally. It is the large hæmorrhagic cysts which may appear to the physician as cases of splenomegaly. It is stated in the literature that a definite history of trauma can often be elicited, and that the cysts are at first serous, and become hæmorrhagic from repeated injury. These points, are not well proven, and there are good reasons doubting them. It is certain that hæmorrhagic cyst may grow steadily, and attain to a large size. Th following is a brief synopsis of a case:—

The patient was a slim girl of 10 years, who was found have a very large spleen, reaching to below the umbilic and extending across the abdomen to the middle line. mass in this situation had first been noticed by a two years previously while the child was being exami during a minor illness. A year later the mass was definite larger, and could be seen as a prominence when the mo was bathing her child. Subsequently enlargement ap to have been progressive but slow. Apart from the enlargement the child was active and healthy, and blood counts and blood films failed to show any real a malities. I did not detect any fluctuation in the For a time nothing was done, since the child was so w and the diagnosis uncertain. Several well-marked attac of perisplenitis, with pain and rough friction, supervened and finally it was decided to remove the spleen. At t my colleague, Mr. Gwynne Williams, was not at all co vinced that the mass was the spleen, as he thought he co detect deep fluctuation in it, and the question of cyst kidney rose. A renal condition was therefore first rul out, and finally the spleen was removed without gr difficulty. It was found to be flattened out over an eno mous single cyst, the wall of which was extremely thin i some places but thick in others (Fig. 9). The contents o the cyst were chocolate in colour and like porridge in consistence. On allowing them to settle in a jar, a opalescent layer separated on top which contained abundant cholesterol crystals.

FIG. 9.



Large hæmorrhagic cyst of the spleen. (This specimen is now the pathological museum of University College Hospital.)

This case illustrates most of the important clinical points.

BACILLÆMIA IN EXPERIMENTAL TUBERCULOSIS,

TOGETHER WITH EXPERIMENTS ON MUTATION AND PATHOGENICITY OF A HUMAN STRAIN OF *B. tuberculosis*.

BY GEORGES DREYER, C.B.E., M.D. COPENHAGEN, F.R.S.,
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF OXFORD;
AND
R. L. VOLLUM, M.A., D. PHIL. OXF.,
UNIVERSITY DEMONSTRATOR IN PATHOLOGY IN THE UNIVERSITY OF OXFORD.

(From the Sir William Dunn School of Pathology, Oxford.)

Introduction.

IT is now probably generally accepted that in clinical and experimental tuberculosis a bacillæmia occurs at some stage of the infection, but the question of when it begins and how long it persists is still unsettled. In cases of generalised miliary tuberculosis it is obvious that the organisms have been carried by the blood stream. In cases where isolated tuberculous lesions occur, as in a kidney, testicle, or joint, and where there is no evidence of direct extension from another tuberculous focus, it is probable that the infection has been carried by the blood.

The first experimental work on this subject is probably that of Villemin (1868), who showed that normal rabbits injected subcutaneously with the blood of a tuberculous rabbit, or of phthisical patients, developed tuberculous lesions. Numerous investigations on the presence of *B. tuberculosis* in the blood have been made since that time, and the literature on the subject has been reviewed in detail by Ishiwara (1923), Calmette (1928), and by Löwenstein (1928). Recently, Bingold (1928) tested the blood of 43 patients, allowing the cells to sediment in 15 per cent. gelatin, and then spreading the deposit on egg medium. He obtained three positive results. Löwenstein and Russeff (1930) planted the centrifuged stroma of hæmolysed blood on a special egg medium containing asparagin instead of peptone. They obtained cultures in all cases of miliary tuberculosis, tuberculous meningitis, and third-stage pulmonary tuberculosis, and in six of eight cases of surgical tuberculosis. Löwenstein (1930) continuing this work, obtained positive blood cultures from 169 of 325 cases—*i.e.*, 52 per cent. His series includes tuberculosis of the lungs, skin, larynx, kidneys, bones, and eyes, and also 21 cases of acute rheumatism, all of which gave positive cultures.

Because of the technical difficulties of cultivating the organisms directly from the blood when they are present in very small numbers, the majority of investigators have had recourse to animal inoculation or to direct microscopic examination of the blood. The percentage of positive results has varied from 0 to 100. The methods based on the injection of the blood or some fraction of it into a test animal are satisfactory if there are sufficient organisms in the blood to infect the animal when doses of reasonable size are injected. Large doses of heterologous blood may be toxic for the guinea-pig, and any vigorous chemical treatment of the blood to concentrate the organisms may be harmful to them. The chief source of error in the direct microscopic examination of the blood is that acid-fast bacilli other than *B. tuberculosis* may be present on the glassware or in the distilled water or other reagent used for hæmolysing the red blood-cells. Another source of error is that small residual amounts of hæmoglobin may cause artefacts which may be mistaken for acid-fast organisms. Furthermore, if the number of acid-fast tubercle bacilli present is very small, as is frequently the case, it is necessary to examine a relatively large quantity of blood—a somewhat tedious procedure.

The relatively small number of successful attempts to obtain cultures directly from the blood is an indication of the difficulty of isolating *B. tuberculosis* on the usual media, and under the usual cultural conditions when only a few organisms are present. One source of difficulty in detecting *B. tuberculosis* in the blood or other pathological material has been revealed by the investigations carried out, particularly during the last few years, into the biology and morphology of this organism. The result of these researches has been to show that the acid-fast organism of Koch's classic description is not the only form in which *B. tuberculosis* occurs. The existence of forms of *B. tuberculosis* other than the usual acid-fast rod may be inferred from a consideration of certain types of tuberculous lesions—*e.g.*, cold abscesses, in which there are very few acid-fast bacilli, although the caseous material is highly infectious for experimental animals. In caseous pneumonia, and in early miliary tubercles, acid-fast organisms may be very rare, and no other organisms may be demonstrated in the histological sections. It is apparent that in such lesions the infecting organism is present in some form not readily demonstrable by the histological or optical methods available.

A considerable number of experiments on record tend to show that the material from such lesions contains a filtrable form of the tubercle bacillus,

analogous to the filtrable viruses. Fontès described a filtrable variant of *B. tuberculosis* in 1910, but it was not until Vaudremer (1923) published the results of his experiments that any extensive interest in the subject was aroused. Since then Calmette, Valtis, and their colleagues have investigated the question, and their conclusions are summarised by Calmette (1930) and Calmette and Valtis (1930). The filtrability of the infecting agent in material from tuberculous lesions has been denied by several authorities—Gloyne, Glover, and Griffith (1929), Cooper and Petroff (1928), and others, and the matter cannot be regarded as finally settled. The literature on the subject has been reviewed by Cooper and Petroff (1928) and by Oluf Thomsen (1929). Löwenstein and Singer (1929) consider that up to the present time there is no stringent proof of the existence of filtrable forms of *B. tuberculosis.* The filtrability of any virus is, of course, a relative term, and unless the type of filter and the conditions of filtration are accurately specified, the value of the results is greatly reduced. The weight of evidence at present appears to be against the filtrability of the infecting material through the finer filters, such as Seitz and Chamberland L 5.

The existence of non-acid-fast forms of *B. tuberculosis* in culture has long been known, and numerous workers, using a great variety of media, have produced more or less non-acid-fast cultures, or have described non-acid-fast forms regularly appearing in cultures (Fontès, 1910; Vaudremer, 1927; Sweaney, 1928; Kahn, 1929). A great variety of non-acid-fast forms have been described, from filter-passing granules to mycelial and yeast-like forms. The variation may be due to a number of factors—different stages in the life-cycle of the bacillus, different media, different strains of bacilli, different methods of experiment, and different degrees of skill in distinguishing artefacts from organisms. The main result of these researches has been to relegate the tubercle bacillus of Koch's classic description to a comparatively minor place in the pathogenesis of tuberculosis. It appears to be a resting stage of the organism and possibly its least active form. If such non-acid-fast forms as occur in cultures were regularly present in pathological material, they should be easily identifiable by the usual bacterial stains. Such, however, is not the case, and it is unlikely that all the morphological types appearing under widely varying cultural conditions in vitro could be found in the relatively constant cultural conditions of the tuberculous lesion.

Experimental.

Culture experiments.—In the course of some experiments on the growth of *B. tuberculosis*, a certain human strain, TB 100, which had been propagated on artificial media for about 30 years, was grown in the depth of ordinary veal-peptone bouillon, prepared as follows:

> To 5 kilos minced lean veal add 10 litres distilled water. Boil 30 to 60 min. Filter. Add 100 g. Witte peptone and 50 g. NaCl. When the peptone and salt is dissolved, adjust the reaction to pH = 6·8. Boil 30 min. Filter through paper. Dispense 500 c.cm. quantities into litre flasks. Autoclave 10 min. at 10 lb. pressure.

A fairly heavy inoculum was submerged in this medium, and incubated for three months at 37° C., when the culture started to grow in the form of small granules at the bottom of the flask. The supernatant liquid remained clear, and there was no growth at the surface. The granules varied in size, up to about 2 mm. in diameter. When growth had started, a few of the granules were transferred to other flasks containing 500 c.cm. of the medium, by means of a Pasteur pipette. A series of subcultures has been carried on in this way for three and a half years, and during that time there has been no tendency to produce a typical surface growth. The rate of growth varies greatly in the different subcultures, probably depending on some uncontrolled factor in the medium. As a rule there is a definitely visible increase in the number of granules after three weeks, although the maximum growth may not be attained for three months or even longer. At times there may be an enormous increase in the number of granules, which remain quite small in size, while at other times the increase in the number of granules may be slight, but the small granules in the inoculum may grow to 3 or 4 mm. in diameter. In this case they usually become much darker in colour, whereas in the former type of growth the granules tend to be quite light in colour. Similar cultures have been obtained in the same way from two other strains of human origin, and from two strains of B C G, which are claimed to be of bovine origin. Cultures grown in this way *in the depth of the bouillon are referred to throughout* this paper as "deep cultures."

Microscopically, the granules in the deep cultures consist of acid-fast rods together with a considerable proportion of non-acid-fast organisms. If a smear of a small granule is stained by Ziehl-Neelsen in the usual way, and counterstained with methylene-blue or malachite-green, there is considerable variation in the amount of stain retained by the acid-fast bacilli and in the intensity with which the non-acid-fast bacilli take up the counterstain. Some of these are a deep blue, while others are so faintly stained that they can be distinguished only with difficulty. If instead of counterstaining in the usual way, a wet preparation is made by placing a drop of dilute methylene-blue on the fixed smear previously stained with carbol-fuchsin and decolorised with 25 per cent. H_2SO_4 and alcohol, and a coverslip placed over the methylene-blue, *a much greater proportion of non-acid-fast organisms can be seen.* There is still considerable variation in the intensity of staining, some being only faintly tinged, while others are a deep blue. The depth of colour continues to increase for about an hour after the stain is put on the slide, and more and more organisms take up the stain and become visible as time goes on. If a certain field be marked, and then the coverslip removed, and the excess stain washed off with distilled water and the marked field re-examined, it will be seen that the greater number of very faintly staining rods, and even some of those more deeply stained, have lost their stain and are no longer visible. On adding another drop of methylene-blue and replacing the coverslip they again come into view. These faintly staining rods, even when treated for 24 hours at 37° C. with a 1 per cent. solution of methylene-blue, fail to retain the stain on subsequent washing with distilled water.

If a thin preparation from an actively growing culture be examined in the wet stain, numerous pairs of bacilli in a "V" or parallel arrangement may be seen, of which one is usually more or less acid-fast, while the other has taken up the counterstain. The non-acid-fast rod may vary in size and intensity of staining from a very thin, pale, scarcely visible rod to a deep blue bacillus as large as the acid-fast one to which it is attached. This arrangement occurs so regularly that it seems highly probable that the non-acid-fast member has grown directly from the acid-fast one, and that it increases in size and intensity of staining with age. In the very early stages it takes up very little, if any, stain even in a wet preparation, and does not retain the stain at all when washed with water.

Similar "chromophobic" bacilli may be found, but to a less extent, in most cultures of *B. tuberculosis* grown on the usual media. Also, they can frequently be detected in wet-stained histological sections of tuberculous tissue, but in this case it is difficult to differentiate them with certainty from tissue debris. We are of the opinion that these non-staining organisms are of the greatest importance in the biology of the tubercle bacillus, and in the ætiology of rapidly progressing tuberculous lesions. The bacterial cells in the early stages, whether growing in culture or in a tuberculous lesion, are incapable of taking up and fixing the stain. In this stage they are so small that it is possible that they might pass through a filter which would hold back most bacilli. As they increase in size and age they acquire the property of fixing the stain, and eventually become acid-fast. They may, however, reproduce, giving rise to other "chromophobic" rods long before the acid-fast stage is reached.

From the study of four strains of *B. tuberculosis* which we have grown and examined in this way, we have never obtained any evidence that, under the conditions of our experiments, the microscopic granules which are occasionally seen are anything other than fragments of degenerating or dead bacilli. This is in accordance with the findings of Gardner (1929).

VIRULENCE OF DEEP CULTURES.

Cultures of *B. tuberculosis* grown in the manner above described were occasionally, but by no means invariably, very much more virulent than cultures of the same strain grown on Petroff's medium. The first strain studied, TB 100, is not usually highly virulent, as has been evident from a number of experiments in which it has been used during the last ten years. A typical example of its low virulence is shown in Expt. 1. Its mutation to a more virulent organism is shown in Expts. 2 and 3.

EXPT. 1 (July 4th, 1927).—Six guinea-pigs were injected subcutaneously on this date with 1/25th mg. of a 12 days' old culture of TB 100 on Petroff's medium. This dose contained about 1,600,000 bacilli. Five of these guinea-pigs *died in* 283, 342, 366, 670, and 794 days respectively. The sixth guinea-pig, three years after the injection, was in good condition and showed no evidence of infection other than enlarged inguinal and axillary glands, and a weak intradermal reaction to old tuberculin. It was killed 1269 days after infection. The post-mortem findings of these animals are recorded in Table I.

EXPT. 2 (Feb. 6th, 1928).—In this experiment the fifth deep subculture in bouillon of TB 100 was used. In the culture, 60 *days old, there was no typical surface growth*, but on careful examination by reflected light a very thin film resembling a film of dust could be seen on the surface of the bouillon. By transmitted light it was invisible. No acid-fast organisms were found in a loopful of this film. Some of the film was skimmed off, taking care not to disturb the granules at the bottom of the flask. Fresh bouillon flasks were inoculated with part of this material, and the remainder shaken up to obtain a homogeneous suspension, and used *for the injection of eight* guinea-pigs, Nos. 226 to 233. Two of the guinea-pigs injected subcutaneously with 1 c.cm. died 16 days later, with an intense hyperæmia of the intestines, but no visible tuberculous lesions. A few acid-fast bacilli were found in the inguinal glands, but none in any organ. Cultures of the heart blood were made in bouillon and glycerin bouillon, and on agar, serum agar, and Petroff's medium. Within three days there were tiny colonies of *B. tuberculosis* visible on the solid media, and the clot in the liquid media contained innumerable acid-fast bacilli. The cause of death in these animals was, therefore, an acute *B. tuberculosis* septicæmia. The remaining guinea-pigs survived the acute phase of the infection. Three, killed after 23, 37, and 348 days respectively, had typical tuberculous lesions. The other three *survived for* 423, 591, and 900 days respectively, and had very slight lesions *post mortem*. (Table I.).

EXPT. 3 (Feb. 29th, 1928.)—One of the bouillon flasks which had been inoculated with the *film from the fifth* deep subculture used in Expt. 2 showed a similar film and a very slight powdery sediment after three weeks' incubation. This flask was shaken up to obtain a homogeneous suspension of the film and sediment. Ten c.cm. of the suspension was centrifuged, and the whole of the deposit smeared on two slides. After staining by Ziehl-Neelsen, the whole of each smear was carefully examined. The total number of acid-fast organisms *in the two slides* was 36—i.e., 3·6 per c.cm. Numerous faintly staining rods were seen in a wet methylene-blue preparation. Twenty guinea-pigs were inoculated subcutaneously *with* 2 *c.cm. of* the suspension—i.e., probably seven to eight acid-fast organisms, and an undetermined number of "chromophobic" bacilli. Two, killed after 6 and 57 days respectively, had only slight tuberculous *lesions*, but cultures of *B. tuberculosis* were readily obtained from the heart blood. No. 321 died of acute generalised miliary tuberculosis in 15 days; the blood culture was positive. Practically all the animals lost weight rapidly and became limp, but the majority survived the *acute phase* of the infection. Six died in 255, 525, 583, 502, 643, and 805 days respectively. Eleven are still alive, 34 months after infection. (Table I.).

TABLE I.—*Guinea-pigs Infected with Various Cultures of TB 100.*

The explanation of the sign (†) is given in the text on p. 1020.

s.c. = subcutaneously; i.p. = intraperitoneally. GT. = generalised tuberculosis. *TB*† = *B. tuberculosis present.* K. = killed. * = no culture taken.

Expt. 1.—TB 100 culture on Petroff's medium, 12 days old.

Expt. 2.—Film from surface of fifth deep subculture of TB 100, 60 days old.

Expt. 3.—Sixth deep subculture of TB 100, 23 days old.

EXPT. 4 (Feb. 29th, 1928.)—Two groups of three rabbits were injected intravenously in the left ear with doses of 2 c.cm. and 5 c.cm. respectively of the same suspension used in Expt. 3. They were bled for culture from the marginal vein of the right ear on March 19th, 1928, 19 days after infection, and cultures of *B. tuberculosis* were obtained from all. They were bled again 33 days after infection, and positive cultures were obtained from four of the six rabbits. The finding of positive blood cultures 19 and 33 days after injection of a human strain of *B. tuberculosis* to which the rabbit is highly resistant indicates that these organisms, when introduced, not only survive but multiply at a considerable rate, probably in the "chromophobic" stage. The total number of acid-fast bacilli injected into each animal was less than 20—i.e., one bacillus to about 5 c.cm. of blood. As the amount of blood taken for culture was only about 0·25 c.cm., it is obvious that the acid-fast bacilli actually injected, if they all remained evenly distributed in the circulation, would be insufficient to account for the positive blood cultures. Three of these rabbits which died, and one which was killed, had no visible tuberculous lesions. The other two are still living. (Table II.).

TABLE II. (Expt. 4, Feb. 29th, 1928).—*Rabbits Infected Intravenously with Sixth Deep Subculture of TB 100.*

Rabbit No.	Dose (c.cm.)	TB in blood culture.		Days lived.	Post mortem
		19/3/28	2/4/28		
154	5	†	0	Alive 8/1/31	—
155	5	†	†	"	—
156	5	†	†	70 (K.)	No macroscopic TB.
157	2	†	†	526	
158	2	††	†	939	
159	2	†	0	172	

Considering the low degree of virulence of TB 100, as seen in Expt. 1, where the infecting dose of 1/25th mg. contained about 1,600,000 bacilli, yet none of the guinea-pigs died acutely, it seems improbable that the very small number of acid-fast organisms—from 4 to 20—present in the infecting doses of the cultures used in Expts. 2 and 3 would be sufficient to cause the lesions found in some of the guinea-pigs. The non-acid-fast "chromophobic" bacilli in the cultures were therefore probably the cause of the infection in these animals. The type of infection produced in some of these guinea-pigs is analogous to the clinical type of tuberculosis first described by Landouzy in 1883 as "typho-bacillose" (Landouzy, 1908). Clinically, this is an acute infection resembling enteric fever, rarely fatal in the acute stage, but some time after an apparent recovery the patient develops well-defined, typical tuberculous lesions in some organ. If death occurs in the acute phase, no typical localised tuberculous lesions are found, but only the diffuse congestion and degeneration common to all acute septicæmias.

Guinea-pigs 232 and 233, which died 16 days after infection without localised tuberculous lesions, but with a *B. tuberculosis* septicæmia, are examples of fatal termination in the acute phase. The others survived the acute phase during which they became limp and lost weight. Some of these eventually developed typical tuberculous lesions, while a few have apparently recovered.

Rapidly developing fatal tuberculous septicæmia in experimental animals inoculated with *B. tuberculosis* is probably a more common experience than is usually recognised. In the course of experiments during the last eight years, numerous groups of guinea-pigs have been infected with various strains of *B. tuberculosis*. A certain number of these animals have died within 3 to 18 days, showing no sign of tuberculous lesions, and either none or very few acid-fast bacilli in the glands and organs. The characteristic post-mortem appearance has been an intense hyperæmia of the abdominal viscera, with occasionally some hyperæmia or congestion of the lungs. Cultures of the heart blood in bouillon were regularly made from these animals, to ascertain whether or not death was due to an intercurrent infection. These cultures remained clear after 14 days, and as platings from them showed no growth, they were rejected as sterile. However, in the absence of any evidence of secondary infection, or of other obvious cause of death, the death has been ascribed to the tuberculous infection. The first positive evidence that these deaths were due directly to the *B. tuberculosis* was obtained from the positive blood cultures from the two guinea-pigs above mentioned, Nos. 232 and 233.

Tuberculous infection of this acute type has been described by Jousset (1908), who reported rapid death without typical tuberculous lesions in 15 of 100 guinea-pigs. He found *B. tuberculosis* in the blood of these animals, both microscopically and by the injection of other guinea-pigs. Three similar cases of premature death in guinea-pigs infected with tuberculous material have been reported by Brindeau, Cartier, and Pougin (1930). These authors agree with Jousset that in the testing by animal inoculation of suspected tuberculous material, one may be misled by this atypical course of the infection.

A factor of considerable importance in experiments involving tuberculous infection in guinea-pigs is clearly seen in our own and other experiments, which show that quite apart from any question of the virulence of the infecting organism, there is an enormous difference in susceptibility between individual animals of the same stock, and in some cases, even of the same litter and the same sex. In Expt. 3, for example, where 20 guinea-pigs, all white, of the same stock, were injected subcutaneously with 2 c.cm. of the same suspension, one died in 15 days with generalised miliary tuberculosis; six died in from 255 to 805 days, and 11 are still alive after [illegible] months. In an important paper by Uhlenhuth and Seiffert (1930), dealing with experiments on tubercle bacilli of low virulence, including B C G, attention is drawn to this very striking difference in the sensitivity of guinea-pigs.

Blood Cultures.

Since obtaining cultures of *B. tuberculosis* from the blood of the two guinea-pigs Nos. 232 and 233, cultures from the heart blood have been taken as a routine from practically all animals dying after infection with *B. tuberculosis*. In the course of this work it was found that solid media were not very suitable, cultures being rarely obtained on Petroff's medium or on glycerin agar unless there was a massive infection in the blood stream, and even in these cases the growth appeared to be better in the liquid media. For all the later work, bouillon and glycerin bouillon alone were used. The post-mortem technique followed in making the cultures is as follows:

The skin of the animal is reflected from the thorax and abdomen without opening either the thoracic or abdominal cavities. The thorax is then opened with sterile instruments, the heart seized with sterile forceps, the pericardium opened, and the surface of the ventricles seared with a hot iron. One of the ventricles is then punctured with a Pasteur pipette, and the blood is withdrawn. This technique may be applied only if the autopsy is made soon after death. If the animal has been dead long enough to allow the blood to coagulate, the apex of the heart is cut off, and a portion of the clot removed with sterile forceps. From 0·1 to 0·5 c.cm. of blood is added to 10 c.cm. of bouillon. Positive results have been obtained with quantities of 0·1 to 1 c.cm., but 0·3 to 0·5 c.cm. is probably the most suitable amount. After incubating for 14 to 60 days at 37° C., the clot, or a portion of it is crushed between two slides, smeared out, dried, fixed by gentle heating, and stained by Ziehl-Neelsen.

If no acid-fast organisms are found in the small portion of the clot thus examined, the whole clot is treated according to the method of Douglas and Meanwell (1925) for demonstrating *B. tuberculosis* in milk, pus, &c.

In staining smears of the clot, the hæmoglobin tends to resist decolorisation, and the preparations are not always satisfactory. The following modification of the staining procedure gave better results. Fix by gentle heating. Pour on carbol-fuchsin and heat until the steam rises; leave for 5 to 10 minutes. Wash in water. Treat with 25 per cent. H_2SO_4 for 30 to 60 seconds. Wash in water. Treat with a saturated solution of picric acid in 95 per cent. alcohol until no more red colour comes out. Then wash in acetone until no more red colour comes out. If necessary, repeat the treatment with picric acid and acetone. The smear usually retains enough picric acid to act as a counter-stain, but if it does not appear yellow, it is stained for 30 seconds in a half saturated aqueous solution of picric acid.

In the later experiments, direct smears of the heart blood have been examined for *B. tuberculosis* if the blood had not coagulated before the post-mortem examination. The technique used is as follows: A reasonably thick, even film of blood is made by the usual method of preparing blood films, and dried for 30 minutes in the incubator at 37° C. Fix very lightly by flaming. Wash very carefully in distilled water, or in 1 per cent. acetic acid until the hæmoglobin is entirely removed. This can only be done if the slide is not too dry. Dry again in the incubator. Fix by flaming, and stain by Ziehl-Neelsen, using picric acid as a counterstain. Occasionally, acid-fast bacilli could be detected, usually within the leucocytes.

Expt. 6C.—Cultures of *B. tuberculosis* recovered from testis and lung of G.-p. 526. Ten days old subcultures injected into fresh guinea-pigs.

In some cases enormous numbers of acid-fast bacilli were found in the blood cultures within a few days, although none, or very few, could be found by direct examination of the blood. In these cases it appeared highly probable that large numbers of *B. tuberculosis* in a non acid-fast "chromophobic" stage were present in the blood, and that these rapidly developed acid fastness under the conditions existing in the blood cultures.

From the experiments with TB 100 it was apparent that *B. tuberculosis* was very frequently present in the blood of guinea-pigs which had died of tuberculosis, or which were killed at an earlier stage of the infection;

and that cultures could be obtained readily in bouillon by a very simple procedure. To confirm this, blood cultures were subsequently made, post mortem, from the heart blood of practically all guinea-pigs which had been infected with cultures of *B. tuberculosis* for various purposes. The results of these experiments are shown in Tables III. and IV., and a summary of all the blood cultures is shown in Table V. Expts. 5, 6, 6A, 6B, and 6C refer to guinea-pigs infected with cultures of B C G. These experiments were part of an investigation dealing with mutations and pathogenicity of B C G, and are reported in detail in another paper (Dreyer and Vollum, 1931). They are briefly summarised in Table III. to complete the record of the work on blood cultures.

* Excluding animals killed during the experiment.

‡ The 10 guinea-pigs which died in two to four days after infection, from pneumococcal peritonitis have been excluded from the calculations of the average life times, and of the percentage of positive blood cultures. Of these 10, however, positive blood cultures were found in 6.

In Expt. 7 (Table IV.) an attempt was made to immunise guinea-pigs with killed cultures of *B. tuberculosis*. Groups 1 and 2 were immunised with an antigen prepared from a mixture of nine different cultures of human strains of *B. tuberculosis* grown for three to six months on non-glycerinated bouillon containing a small amount of some growth stimulating substance such as yeast autolysate, bacterial extracts, bios, serum, orange-juice, or potato-juice. The growth was filtered off, washed with distilled water and acetone, extracted with acetone in a Soxhlet apparatus for 24 hours; treated with 1 per cent. formic acid in formalin for 24 hours at 56° C., and again extracted with acetone in a Soxhlet apparatus for 24 hours. The bacterial mass was then dried, ground, and suspended in saline containing 0·08 per cent. commercial formalin. The animals were given three doses of 1, 2, and 5 mg. respectively on Feb. 14th, 21st, and 28th, 1928. Group 1 were injected intraperitoneally, and group 2 subcutaneously. Fourteen rabbits were injected intravenously with similar doses of the antigen at the same time. The guinea-pigs were tested intradermally with old tuberculin on April 2nd, 1928, and all gave a strong positive reaction.

For the immunisation of groups 3 and 4, the non-acid-fast culture of TB 100 used to infect the guinea-pigs in Expt. 3, was killed by the addition of 0·1 per cent. formalin, and doses of 2, 3, and 5 c.cm. respectively were given on March 22nd, April 2nd, and April 18th, 1928. Group 3 were injected intraperitoneally and group 4 subcutaneously. These 62 guinea-pigs, together with 62 normal controls, were infected May 25th, 1928, by intraperitoneal injection of 1/25th mg. of a virulent bovine strain, *B. tuberculosis* Cockhorn, which had been grown on Petroff's medium for one week. All of the guinea-pigs were bred in this department; they were all white, of the same stock, and of approximately the same age. Three of the controls and seven of the immunised guinea-pigs died of an acute pneumococcal peritonitis within four days after infection. The source of this intercurrent infection was not traced.

The infecting dose used was probably too severe a test to allow of any striking difference between the control and immune animals. Eliminating those which died of pneumococcal peritonitis within four days of receiving the infecting dose of *B. tuberculosis* the average life-time of the controls was 57 days. The average life of the guinea-pigs in groups 3 and 4 was only 50 days. The amount of antigenic substance in the culture used for immunising these animals was very small, and apparently the only result of the treatment was to make them hypersensitive. The average life of the guinea-pigs in groups 1 and 2, however, was 73 days, 28 per cent. longer than the controls. The average life of the group of 14 immunised rabbits was 124 days, while the average life of 14 controls was 81 days. The life of the immune rabbits was therefore 53 per cent. longer than that of the controls. This antigen produced a certain degree of immunity, which was apparent even under the rather severe conditions of the test.

The results of the examination of the blood cultures are recorded in the Tables. The relative numbers of acid-fast bacilli are indicated by one or more signs as follows: (†) indicates very few individual organisms, less than six being found after one hour's search; † indicates individual organisms in larger numbers, and more readily found; †† indicates that clumps and small colonies were found as well as individual bacilli; ††† indicates large numbers of clumps and colonies readily found with the low power of the microscope.

The results of the examination of the blood cultures from all guinea-pigs infected with TB 100, B C G, and TB Cockhorn are summarised in Table V. From this Table it is seen that, as a rule, the average life of guinea-pigs from which positive blood cultures have been obtained, post mortem, is considerably shorter than the average life of guinea-pigs similarly infected which did not give positive cultures. This difference is maintained whether the average life is short, as in Expt. 7, or prolonged as in Expts. 1, 2, and 3. It seems not unlikely that the increased resistance developed during the course of the disease in the longer living animals tends to prevent the bacillæmia, or the growth of the bacilli in the blood culture. This is borne out by the fact that among the immunised guinea-pigs of groups 1 and 2 in Expt. 7, only 70 per cent. gave positive blood cultures, while of the normal controls 93·2 per cent. gave positive blood cultures.

Summary.

From an examination of the experimental data the following facts emerge:—

1. That animals infected subcutaneously, intraperitoneally, or intravenously with *B. tuberculosis*, regardless of the virulence of the strain, have a *B. tuberculosis* bacillæmia in a very high percentage of cases. Of 182 animals, 160 gave positive cultures from the heart blood post mortem—i.e., 87·9 per cent.

2. That from animals whose resistance to infection has been increased by vaccination, a smaller proportion of positive blood cultures is obtained than from normal animals infected at the same time with the same dose of *B. tuberculosis*. Thus in Expt. 7, from 59 control guinea-pigs with an average life of 57 days, 55 positive blood cultures were obtained—i.e., 93·2 per cent. From 30 vaccinated guinea-pigs with an average life of 73 days, 21 positive blood cultures were obtained—i.e., 70 per cent. From a group of 25 guinea-pigs where vaccination resulted only in greater sensitiveness to infection, the average life being 50 days, 24 positive blood cultures were obtained—i.e., 96 per cent. Thus there is an indication that vaccination which produces a higher resistance results in a considerable decrease in the percentage of positive blood cultures.

CONCLUSIONS.

1. A bacillæmia is a regular occurrence in guinea-pigs infected with *B. tuberculosis* of human or bovine type, of high or low virulence. From 152 guinea-pigs, including controls and unsuccessfully vaccinated animals, positive blood cultures were obtained in 91·4 per cent.

2. In any group of animals under similar experimental conditions, infected with the same dose of the same strain of *B. tuberculosis*, positive blood cultures are less frequently obtained from those which live longest, although in these the tuberculous lesions are usually more pronounced.

3. From the experiments detailed, it seems likely that the "chromophobic" (unstainable, or mostly unstainable, and therefore also non acid-fast) tubercle bacilli are of the greatest importance in the development of tuberculosis, experimental or clinical. This is supported by the frequency with which positive blood cultures are obtained when no acid-fast organisms can be detected in direct smears of the blood.

Our thanks are due to Mr. Jesse Wheal and Mr. J. L. Nappin for their painstaking care of the animals during these experiments. One of us (R. L. V.) is greatly indebted to the Medical Research Council for a part-time grant.

THE DE-AMINISING POWER OF THE BLOOD IN CANCER WITH REGARD TO ARGININE.

By ALEX. HADDOW, M.B. EDIN.,
ASSISTANT IN THE DEPARTMENT OF BACTERIOLOGY, UNIVERSITY OF EDINBURGH.

IN 1904 Kossel and Dakin [1] showed that liver tissue possesses an enzyme which they termed arginase and which hydrolyses arginine to ornithine and urea. Clementi (1916, 1918, 1922),[2] Hunter and Dauphinee (1924),[3] and Edlbacher and Rothler (1925),[4] have made a compehensive survey of the natural occurrence of arginase in mammals, birds, and fishes. Edlbacher and Merz (1927)[5] stated that the ferment was absent from most normal tissues save liver, kidney, testis, and placenta, although they have apparently found the enzyme in some species in the red corpuscles.

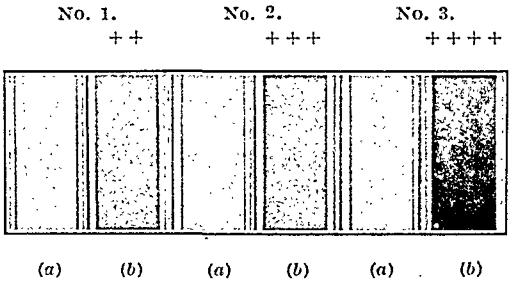
From the Heidelberg laboratory Edlbacher and Merz [5] have recently shown that "all malignant mammalian and human tumours, whether carcinomas or sarcomas, are distinguished from normal tissue by their arginase content." This fact is the more interesting in that there is apparently no sign of a general increase in de-aminising power, other amino-acids not being decomposed. The work recorded in this preliminary report has been an attempt to ascertain whether this metabolic property is reflected in the blood.

Preliminary titrimetric results indicated that if the enzyme is present in the blood in any given case it is, as might be expected, in a concentration very low when compared with that in, say, the mammalian liver or in the tumour tissues examined by Edlbacher and Merz. It has become evident that the positive detection and estimation of arginase under these conditions demands a method of urea determination of great precision. In this work the urease method has been used, followed by indirect nesslerisation.

The preparation of the substance to be examined for arginase varies in the experiments of different workers. Edlbacher and Merz allowed unextracted minced tissue to act directly on an arginine solution, and in the present research blood has been used in the same way.

On the assumption that arginine de-amination if present may be a function of a single element of the blood and that no inhibitory mechanism may reasonably be expected to exist in any other element, in the first instance use has been made of whole blood prevented from clotting by addition to a suitable volume of 2 per cent. sodium citrate in 0·85 per cent. saline. Five c.cm. of fresh citrated blood is accurately measured into each of two sterile test-tubes. To one of these is added 5 c.cm. 1 per cent. arginine in sterile distilled water and to the other an equal volume of the solvent. For the purpose of establishing a series of experiments under these conditions, no account was taken of the resultant pH difference in the tubes at this stage. In practice it has been found that any increase arising from this cause in the blood-urea or ammonia nitrogen in the test specimen as compared with the control is apparently absent or slight. After 1 c.cm. toluol has been added to each tube, these are then stoppered and incubated at 37° C. for a given period, say 24 hours.

—	No colour difference between control and test Nessler,
+	Relative intensification of test Nessler just perceptible.
+ +	Moderate intensification of test Nessler.
+ + +	Very definite intensification of test Nessler.
+ + + +	Strong intensification of test Nessler.



Photographic representations of the colour change in 30 c.cm. of Nessler's reagent, with the value assigned to each. Tube (*a*) in each of the examples represents the control sample, and in these cases was a varying shade of yellow. Tube (*b*) represents the urea in the test sample. In No. 2 it was light amber, and in No. 3 light brown

In the present work use has been made of a sensitive modification of Nessler's reagent containing 7 per cent. final concentration of alkali. The main difficulty encountered is that after completion of aeration the Nessler tubes, while affording an approximate naked-eye comparison, are quite inadequate for accurate colorimetric work on a quantitative scale. This is due to the precipitation of the colloidal coloured ammonia compound formed, and the fault has been investigated and corrected.

Results of Clinical Test.

The conditions examined to date are cases from a general surgical ward, and while the composition of the non-malignant group is not sufficiently varied and does not include examples of the main medical systemic diseases, nevertheless the results obtained so far are sufficient to warrant a preliminary report. The diagnoses were based on clinical, operative, and pathological data, and the results were as shown in the following Table.

The results tabulated may also be stated in the following way. The malignant cases yielded 5 strong results, 13 definite, 7 moderate, 5 weak or doubtful, and 2 negative. The non-malignant cases yielded 18 negative results, 7 weak or doubtful, and 1 moderate. Two cases of doubtful diagnosis as regards malignancy gave a negative and a doubtful result.

The most striking result was that given by Case 5. Clinically this case was remarkable for the extent of the malignant deposits in the cervical glands, and microscopically the tumour was found to possess intense proliferative activity. Case 44 is of interest in that a very definite presumptive indication of the presence of arginase in the blood was obtained before treatment, although clinically the case was definitely regarded as non-malignant. At operation the condition was found to be a carcinoma of the head of the pancreas. A similar instance was found in Case 33, where a positive reaction was obtained. At operation a large gastric ulcer was found with local characters so strongly suggestive of malignancy that arrangements were made for ultimate resection.

Further Inquiry.

The data are inadequate for the determination of the relation to the reaction of the stage of the disease or the results of treatment, but one gains the impression that extensive deposits in the lymphatic glands may lead to a leakage of the ferment into the blood stream as an appreciable trace. Investigation requires to be extended in order to define the precise limits of the reaction regarded as a possible diagnostic aid.

Cases 45–60 have been dealt with by modifications of the method described above. Certain cases have been investigated in an attempt to potentiate the action of any arginase present in the blood. Hunter and Dauphinee showed that pH 7·4 (approximate blood reaction) is about the middle of the range over which arginase shows a rising activity, the optimum being at about pH 9·8. Accordingly, tests were arranged in which the incubation was carried out at this latter level, after which the pH was brought back to 7·4 by the addition of phosphate buffer solution prior to the urea estimation. So far the results of this procedure have been inconclusive. From a few cases in which serum has been used it appears that the ferment if present in whole blood is also present in the serum. With regard to time and the completion of the reaction, it appears that incubation should last for at least 24 hours.

Other cases have been used to endeavour to refine the procedure so as to produce crystal-clear Nessler solutions for accurate colorimetric work. Direct nesslerisation was found to be unsuitable, and the best result so far has been obtained by aerating through a measured volume of $HgI_2.2KI$ solution and making up to a suitable volume by the addition of N/2 NaOH. By this method a test on blood from a malignant case revealed an apparent arginine split of 6 per cent. when examined in a Klett colorimeter. It is also proposed to aerate into a known volume of N/100 H_2SO_4 and utilise this for direct nesslerisation. If by such a method one can arrive at an accurate colorimetric technique, it will greatly facilitate the collection of results on a definite quantitative basis.

I have to acknowledge the encouragement which Prof. T. J. Mackie has given me in the course of this preliminary work, and my thanks are also due to Prof. J. Fraser and Prof. D. P. D. Wilkie for their kindness in giving facilities for the collection of material.

Summary.

(1) A method is described which has been used for the comparison as to urea content of equal volumes of citrated blood incubated under conditions of sterility in admixture with equal volumes of (*a*) 1 per cent. arginine; (*b*) sterile distilled water.

(2) Preliminary results have pointed to the existence of a significant increase in urea concentration when blood from certain cases of malignant disease is incubated under these conditions with arginine.

(3) The presumptive evidence suggests that the effect produced may be attributed to the presence of a trace of arginase in the blood. This suggestion is in no case completely confirmed in so far as the ferment has not been separated from the material examined and destroyed in a control, say by boiling.

(4) The maximum effect has been observed in well advanced cases of malignant disease, particularly in those exhibiting marked involvement of lymphatic glands.

(5) The tentative suggestion is made that a test based on the observation recorded might be utilised for diagnostic purposes.

MARIE CELESTE SAMARITAN SOCIETY.—This society which was founded in 1791 by Sir William Blizard, surgeon to the London Hospital, exists to supplement the work of the institution; last year it assisted 11,572 patients in various ways. Thus surgical appliances were provided to the number of 4623 at a cost of £5827, towards which patients and their friends paid £2519. The total number of patients sent away to various homes and sanatoriums was 2303, an increase of 372 on the preceding year.

THE SERUM TREATMENT OF LOBAR PNEUMONIA.

BY C. F. TERENCE EAST, D.M. OXF.,
F.R.C.P. LOND.,

PHYSICIAN TO KING'S COLLEGE HOSPITAL; PHYSICIAN TO THE WOOLWICH MEMORIAL HOSPITAL.

THIS paper records results obtained by treating patients suffering from lobar pneumonia with the polyvalent serum made by the Lister Institute. As soon as the diagnosis was made, and opportunity offered, the patient was given antipneumococcal serum either subcutaneously or intramuscularly. Sometimes two or three doses were given of 25 c.cm. each.

Typing the pneumococcus is not usually a practical proposition when patients are ill in their own homes, and even with full laboratory facilities in a hospital a good deal of time must necessarily be lost before the type is ascertained. It is universally recognised that the sera are generally only useful against type 1 and type 2, but as a very considerable proportion of cases of lobar pneumonia are due to one of these two types, it seems reasonable to give it in the hope that good will result.

Results.

The number of cases treated is not large and of no value for statistical purposes, but the results obtained leave one hopeful that in a considerable proportion of cases of lobar pneumonia the use of antipneumococcal serum may possibly save the patient's life, or at any rate cut short a dangerous and trying illness. Twenty-five cases in all received serum, and 13 of these appeared to derive benefit from it. In the remaining 12 no demonstrable effect was obtained.

Failures.—The cases which were not benefited by the serum are in striking contrast to those that were. Of these 12 patients, three died, one being an alcoholic and likely to die anyway; three developed empyema; four went on until a crisis on the eighth day; one cleared up by lysis about the eighth day, and one had delayed resolution and pneumococcal arthritis. They thus all experienced a long and troublesome illness, possibly with complications, or died.

Successes.—In this group of 13 cases the serum appeared to influence the course of the disease, sometimes in a manner that can only be described as dramatic. Unless one is at the bedside it is not

No.	Sex and age.	Day serum given.	No. of doses.	Day of recovery.	Days in hospital.	Remarks.
1	M., 57	3	3 s.c.	4	—	Severe case; other lung fibroid.
2	M., 40	1	3 i.m.	4	—	Severe case; both lower lobes.
3	M., 37	1	2 s.c.	3	—	—
4	M., 30	2	2 i.m.	3	—	—
5	F., 39	2	1 i.m.	3	12	Severe; resolved four days after effect.
6	M., 38	2	1 i.m.	3	15	Moderately severe.
7	M., 38	2	1 s.c.	3	13	Severe.
8	M., 17	2	1 s.c.	3	15	Fairly severe.
9	F., 14	2	3 i.m.	3	21	Moderate.
10	M., 5	3	3 s.c.	4	9	—
11	M., 6	2	1 s.c.	3	31	—
12	F., 33	5	1 i.m.	6	26	Slow resolution.
13	M., 11	3	2 s.c.	7	16	—

NOTE.—The day given is the day of disease, as far as it could be accurately ascertained. The day of recovery is [illegible] day on which the toxæmia abated and the tem [illegible] Resolution did not necessarily take [illegible] at once. [illegible] muscular injection. s.c. = subc [illegible] possible to show convincingly in every case the good results of serum, but the Table and notes of the cases give an idea of the effects.

CASE 1.—An elderly man, stout and not a good subject; extensive fibrosis being present in the right lung and lobar pneumonia involving the left lower lobe. It seems probable that the serum saved his life.

CASE 2.—Rapid consolidation of the right and left lower lobes appeared in this healthy man, aged 40, and it was evident that the prognosis was hazardous. Toxæmia very severe. The immediate benefit derived from the serum was most striking.

CASE 3.—Man, aged 37. After the second dose of serum there was a crisis on the evening of the third day. A severe toxic case. Left lower lobe affected.

CASE 4.—Left lower lobe affected. Temperature fell after the first dose of serum and reached 99° F. on the evening of the third day after a double dose. Some fever at this level until the seventh day. The course of the disease appeared to be definitely influenced for the better. Patient a man aged 30.

CASE 5.—A severe case. Respirations 36; pulse-rate 110. Immediate effect on toxæmia. Right upper lobe affected. Resolution occurring four days later. Patient a woman aged 37.

CASE 6.—Male, aged 38. Fairly severe toxæmia. Respirations 34; pulse-rate 110. Right lower lobe affected. Rapid improvement after serum. Consolidation never developed. Herpes labialis came later.

CASE 7.—Fairly severe. Definite effect of serum. Left lower lobe affected. Herpes later. Lung cleared on third day. Patient a man aged 38.

CASE 8.—Respirations 40; pulse-rate 130. Left lower lobe. Good effect of serum in 12 hours.

CASE 9.—Very ill. Pulse-rate 120; temp. 105° F. Respirations 38. Right lower lobe affected. Rapid improvement after second dose.

CASE 10.—Right lower lobe affected. Pulse-rate 140; respirations 38. Rapid and obvious improvement after three small doses at short intervals.

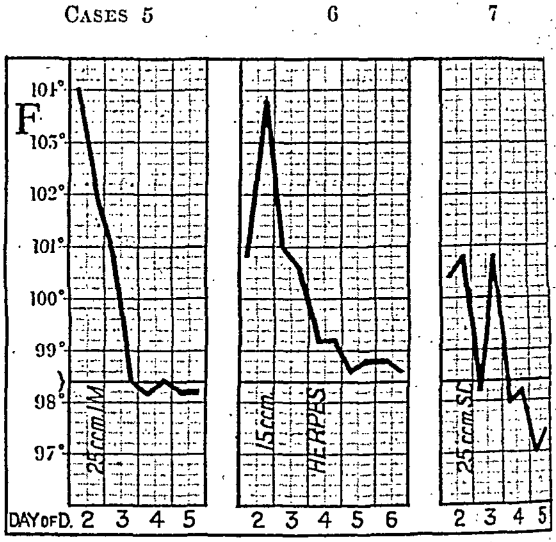
CASE 11.—Vague signs in right lower lobe, but never developed. Pulse-rate 160; respirations 50. Much better the day after serum given.

CASE 12.—Treated rather late. Temperature fell at once after serum was given, and general condition improved. Resolution slow in left lower lobe. In view of this the serum was probably effective, but as it was given rather late the improvement might have been natural.

CASE 13.—Left lower lobe. Moderate case. Possibly doubtful effect, but the patient seemed better after serum.

Comment.

Comparisons.—The incidence of death and grave complications among those patients to whom serum was given, and who were not benefited by it, is fairly high in this small series. As a check upon it is worth while to refer to a series of 14 cases which occurred in hospital before serum was used. Among these 14 cases only one death occurred, and there were no cases of empyema. Two patients had delayed resolution. From this it is evident that consideration of mortality alone, in comparing a series treated with serum with another not so treated, is not necessarily helpful unless the series are very long. One can only go upon a definite change in the course of the disease following the administration of serum, which one would not otherwise have expected. It must also be remembered that in different seasons the character of pneumonia varies, no doubt because of the alteration in the type of pneumococcus prevalent.

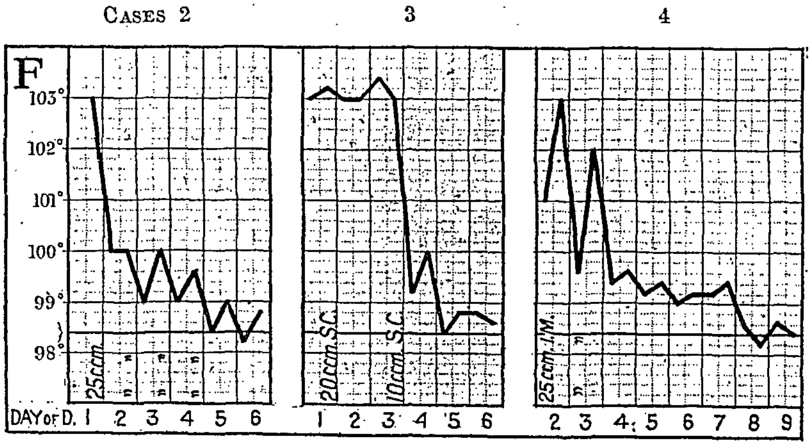


Temperature charts in Cases 5–7.

Good Effects.—Unquestionably the earlier in the disease the serum is given the more complete is the good result, if result is obtained. If one dose has no obvious effect it is worth while to give another or a third. The good effects of the first dose may require to be extended by a further dose. If the temperature has fallen after the first dose, and rises again, a second dose should be given, and so on. The toxæmia is usually controlled quickly in successful cases, and the patient notices the benefit at once. If the consolidation has developed definitely it may take a few days to clear up; but if the serum has been given early, the pneumonic process may subside rapidly and very little consolidation take place.

Ill-effects.—Only one patient had a serum reaction about the tenth day, which was easily controlled by adrenalin. There were no untoward effects apart from this.

Remarks.—From these results it seems reasonable for any practitioner treating a patient for lobar pneumonia to give a polyvalent antipneumococcal serum either intramuscularly or subcutaneously. The technique of intravenous injection is not at the command of everyone,



Temperature charts in Cases 2–4, showing amounts of serum injected (S.C. = subcutaneously and I.M. = intramuscularly). The day of disease is indicated at the bottom of the charts.

and the administration of large doses of serum intravenously is apt to produce reactions which are disturbing. The results suggest that treatment on the lines employed, which are simple, will procure benefit to a certain number of patients suffering from lobar pneumonia; certainly no harm can result even if the case is one which does not respond to serum owing to the infecting organism being of the wrong type of pneumococcus.

Even if a patient is saved two or three days of severe illness something is gained, and convalescence and absence from work are shortened. The anxiety of the patient, his friends, and medical attendant may be greatly diminished. It appears that the serum therapy of lobar pneumonia, whatever form of serum finally turns out to be the best, will give a potent weapon in the treatment of a considerable number of cases of a disease which the medical man has hitherto been so helpless to control.

NOTE ON THE TREATMENT OF CANCER OF THE RECTUM.

By P. Lockhart-Mummery, F.R.C.S. Eng.,
SENIOR SURGEON, ST. MARK'S HOSPITAL FOR DISEASES OF THE BOWEL.

There seems to be a very general belief that the treatment of cancer of the rectum, which is one of the commonest forms of cancer in this country, is very unsatisfactory, and it is even stated by some people that there is no real cure for the condition by modern methods, and that patients would be almost as well off if they were left untreated once they have been found to be suffering from a rectal cancer. This view is, of course, very far from the truth, though, at the present day, over 50 per cent. of the cases brought to the surgeon are already too far advanced for there to be any reasonable chances of a cure.

There are at the present time two chief methods of treating cancer of the rectum which hold out hope of curing the patient. These are by removal of the growth by operation, and by treating it with radium needles or radon seeds. The figures given here relate only to cases of carcinoma of the rectum treated by operation under my own method of perineal excision and operated upon by myself. No cases treated by abdomino-perineal excision are included. This latter operation for the treatment of rectal cancer I now reserve for those cases where it is impossible to remove the growth by the perineal route on account of its height, size, or other causes, and such cases only form a small proportion of the whole. The total number of cases of cancer of the rectum in this series, operated on by the perineal route, is now 300, and very many of them have been traced for periods over five years. No account is taken of cases operated upon less than five years ago, except in estimating the operation mortality. No special selection of cases has been made, and any case in which the growth was removable without exceptional risk was operated upon.

The ages of the patients varied from 29, the youngest, to 79, the oldest. The latter patient is still alive and well, and is now 81. Many of the patients had complicating disease, such as diabetes, Bright's disease, chronic bronchitis, &c.

That cancer of the rectum can be cured by operative treatment is a statement which I think cannot be contraverted after a study of the following table, which shows the number of patients surviving the operation for a period of seven years or more:—

Patients surviving operation 7 years or more ..	56
„ „ „ 10 „ „ ..	28
„ „ „ 15 „ „ ..	5

As cancer of the rectum is a disease of late life, it is obvious that long periods of survival can only occur exceptionally. A large number of patients who have been operated upon have, of course, died of old age and other causes, apart from cancer of the rectum. As a matter of fact, only one case surviving seven years after operation is known to have died of recurrence of the original growth. It is very difficult to know when we are justified in using the word "cure" in relation to any condition, more particularly when it relates to cancer. But there cannot, I think, be any reasonable doubt that the cases in the above table have, with the exception stated, been cured of the disease. Others also who have died of other causes might have been cures had they survived long enough. We generally assume that any case surviving operation five years is cured, but this period is unquestionably rather too short.

Out of 300 private and hospital cases there are 180 who were operated upon more than five years ago. These work out as follows:—

Cures on five-years basis	84
Recurrences	82
Died from other causes during the five years ..	11
Untraced	3

This gives a proportion of 46·6 per cent. cures. Or if we divide the "died from other causes" cases and untraced cases into their probable recurrence-rate—i.e., roughly 50 per cent.—and add 7 cases to the cures, this would make 180 cases with 91 cures, or a percentage of 50·5 cures. In the cases where the operation was performed when the growth was in the early stage before it had gone through the rectal wall, the proportion of cures was 60 per cent.

The actual risks from the operation have now been so much reduced that they are little greater than for operations in general upon persons of advanced age. Thus out of 150 private cases there were six deaths, or a 4 per cent. mortality.

The chances for any individual patient suffering from cancer and who is operated upon in the early stage, while the growth is still limited to the bowel wall, are roughly these: a 96 per cent. chance of surviving the operation and a 60 per cent. chance of being cured from the disease. I think even the most pessimistic person must admit from these figures that cancer of the rectum is by no means an incurable disease. There are, as a matter of fact, a large number of people living useful and active lives who have been cured of rectal cancer as the result of modern surgery, and the proportion of cures would be very much higher were it possible for all cases to be operated on in the early stages of the disease before spread has taken place beyond the muscle coat. The chief handicap to the cure of rectal cancer is not bad treatment, but bad diagnosis of the disease.

It is not possible yet to estimate accurately the chances of a cure from treatment by radium. All we can say at present is that in some cases the growth has entirely disappeared after the treatment by radium, and the patient has remained in perfect health for a period of a year or more. The cases of rectal cancer suitable for radium treatment are those in which the growth is low down and easily accessible; for growths in the middle of the rectum or high up treatment by means of radium is very unsatisfactory, and although good results have been secured in a few such cases, the results in the majority have not been good. Radium is, however, proving of value in delaying or ameliorating growths which are already inoperable, and as the technique of using radium in rectal cancer continues to improve the results will be better. While I am personally doubtful if radium will ever take the place of excision as a means of curing rectal cancer, except in the case of those growths situated at the lower end of the rectum which are easily accessible, I believe that it will prove of great value as an aid to direct surgery in those cases which at present cannot be cured by excision alone.

THE EFFECT OF

GAMMA RAY IRRADIATION UPON THE RED CORPUSCLES.

By T. Valentine Cooper, M.B. Lond.,
ASSISTANT PATHOLOGIST TO WESTMINSTER HOSPITAL ANNEXE.

Henri and Mayer[1] stated that when radium was allowed to act upon blood corpuscles, partial hæmolysis occurred, which they attributed to "increased osmotic sensitivity." These workers also found that a suspension of hæmoglobin became converted into methæmoglobin.

Working here in connexion with radium, more particularly with the National Radium Commission's 4-gramme "bomb," we observed that if a series of blood counts be performed during the patient's "bomb" treatment, the fall in the red corpuscular count is more marked than the fall in the hæmoglobin percentage. This led me to experiment to see whether increased osmotic sensitivity of the red corpuscles were measurable in vitro.

Ten samples of blood were obtained from patients, only four of whom were suffering from malignant disease. The technique was standardised so that 10 c.cm. of blood from each case was put into a tube containing 50 mg. of neutral potassium oxalate. This salt was present as a fine coating on the walls of the tube after the technique of Beaumont and Dodds,[2] who introduce a solution of the salt and drive off the water in an oven. The bloods, after vigorous shaking, were divided into equal parts, one being exposed at a distance of 1·5 cm. for a period of 48 hours to the "bomb"; the second portion was kept as a control. The fragility was then measured by the sodium chloride method and the readings taken at the end of an hour.[3]

Table I. explains the technique and Table II. shows the results obtained. A standard Dreyer pipette was used throughout.

TABLE I.

Number of drops of 1 per cent. NaCl in distilled water..	7	6	5	4	3	2	1
Number of drops of distilled water	3	4	5	6	7	8	9
Resulting dilution per cent.	0·7	0·6	0·5	0·4	0·3	0·2	0·1

It can be seen that in every one of these cases, a definite increase in fragility has been demonstrated. This finding naturally resulted in further investigations with a view to establishing the cause. Two explanations are open: (*a*) That there is some change produced in the plasma so that its osmotic effects are strengthened and the red corpuscles weakened secondarily. (*b*) That the red corpuscles are altered in some way so that the *normal* plasma osmotic tension has a much increased effect. Finally, the possibility of a combination of these must be considered.

With these queries in mind I irradiated, in the same manner as before, washed red corpuscles in saline suspensions, and the separated plasma. Controls were kept and used as previously. The irradiated corpuscles have been shown repeatedly to be *more* sensitive—e.g., irradiated corpuscles 0·4 + + +, control corpuscles 0·35 + + +. On the other hand, no change has been detectable in the plasma, when varying dilutions of irradiated and control plasma have been added to unirradiated corpuscles and the hæmolysis point determined. This further observation appears to demonstrate that the effects of irradiation fall directly on the red corpuscles and the problem then resolves itself into considering whether the change is on the corpuscular "limiting membrane" or upon their contents.

TABLE II.

Blood of case.	Irradiated.		Control.	
1	0·3 + + +	0·4 + +	0·2 + + +	0·3 + +
2	0·5 + + +		0·4 + + +	0·5 + +
3	0·5 + + +		0·4 + + +	0·5 +
4	0·3 + + +	0·4 + +	0·3 + + +	0·4 +
5	0·4 + + +	0·5 +	0·3 + + +	0·4 + +
6	0·4 + + +	0·5 + +	0·3 + + +	0·4 + +
7	0·4 + + +	0·5 + +	0·3 + + +	0·4 +
8	0·4 + + +	0·5 + +	0·3 + + +	0·4 +
9	0·4 + + +	0·5 + +	0·3 + + +	
10	0·4 + + +		0·3 + + +	0·4 +

+ = Commencing hæmolysis. + + = Partial hæmolysis.
+ + + = Complete hæmolysis. Figures = per cent. saline.

Hæmolysis in a higher strength saline indicates increased fragility.

Now a red blood corpuscle is a relatively inert and non-nucleated body acting physico-chemically as a carrier. First Bohn,[4] subsequently Hertwig,[5] then Mottram,[6] and later, French workers[7] have shown that a cell is most radiosensitive during mitosis; from this it has been assumed that the effects of irradiation fall mainly upon the nucleus when it is in the later phases of mitosis. This period must also be the time when the cell membrane is weakest, as it is then compelled to enlarge its area to enclose the newly forming cells.

In order to provide one explanation for radiosensitiveness of non-nucleated red corpuscles and nucleated cells, I venture to suggest that in both instances irradiation modifies the limiting membrane so that its osmotic selectivity is impaired, and further, that the nuclear phenomena, which have been described by several observers, are in fact secondary changes. Some added weight is given to this theory by the work of Schwarz,[8] who demonstrated that skin, rendered anæmic by pressure, gave a subnormal reaction to irradiation. This suggests that whatever change may occur in the cells, the fullest results only appear in the presence of a free blood-supply. This latter is emphasised by the work of Jolly,[9] who found that a rabbit's popliteal gland was radioresistant following partial curtailment of its blood-supply.

In conclusion, I wish to acknowledge the assistance of Dr. F. D. M. Hocking, who has checked and confirmed my observations.

CLINICAL AND LABORATORY NOTES

PAPILLŒDEMA AND OPTIC ATROPHY FOLLOWING INTESTINAL HÆMORRHAGE.*

BY I. J. FRANKLEN-EVANS, M.B. CAMB.

PAPILLŒDEMA and optic atrophy following hæmorrhage is rare, only 240 cases having been reported in the literature up to 1924 (Harbridge),[1] and comparatively few of these cases have been observed from the onset of the papillœdema.

The two cases recorded developed papillœdema while in hospital. In Case 1 papillœdema was discovered during a routine examination; but although marked secondary optic atrophy supervened, there was no loss of visual acuity whatsoever. Cases previously reported have all begun with sudden loss of visual acuity and there has been marked permanent impairment of sight. A careful search of the London Hospital records back to 1900 yielded only two additional cases of optic atrophy following hæmorrhage; in both cases there was a history of a severe hæmatemesis and sudden loss of sight.

CASE 1.— A boy, aged 17, was admitted to the London Hospital on Feb. 10th, 1928, with a three weeks' history of epigastric pain relieved by vomiting, but there was no hæmatemesis. He had been constipated for three weeks, but there was no melæna. During the next four days he passed dark stools, suffered from diarrhœa, and became very anæmic. A blood count on Feb. 15th showed: erythrocytes, 3,300,000 per c.mm.; hæmoglobin, 46 per cent.; colour-index, 0·7; leucocytes, 4880 per c.mm.; polynuclear neutrophils, 69 per cent.; polynuclear eosinophils, 1 per cent.; small lymphocytes, 25 per cent.; large lymphocytes, 1 per cent.; large hyaline cells, 4 per cent. Anisocytosis and polychromatophilia were present. The patient was given a blood transfusion. On March 1st a widespread œdema of the optic nerve and retina was noted and a week later both right and left eyes showed papillœdema with three dioptres of swelling, and hæmorrhages were present in both eyes. A blood count showed: erythrocytes, 2,200,000 per c.mm.; hæmoglobin, 25 per cent.; colour-index, 0·57; leucocytes, 6400 per c.mm.; blood-platelets, 270,000 per c.mm. The chest, abdomen, and central nervous system were normal; the tonsils were enlarged and pale. He complained of no disturbance of vision.

There was a slight irregular pyrexia; the urine was clear: the Widal test was negative. An X ray report on March 29th stated that a small penetrating ulcer was present on the lesser curvature of the stomach. Before admission to hospital he had taken no medicine except some castor oil; he did not drink, and smoked about ten cigarettes a day.

The patient was first seen by me on August 25th, 1930. He had been perfectly well since he was in the London Hospital in 1928 and had had no trouble with his eyesight. In the right eye, vision was 6/6 and marked secondary optic atrophy was present, with sheathing of the vessels on the disc. The physiological cup was filled. Examination on this day showed in the left eye, vision was 6/6 and some sheathing of the vessels on the disc was present, with indistinctness of the margin up and in. The physiological cup was filled. There was no scotoma or constriction of the visual fields. The central nervous system showed no other abnormality.

CASE 2.—A boy, aged 16, was admitted to the London Hospital on July 28th, 1928, in a pale and shocked condition, having had four profuse hæmorrhages from the rectum in the last 24 hours. An examination was negative except that the liver was enlarged 1 in. below the costal margin. A blood count showed: erythrocytes, 2,600,000 per c.mm.; hæmoglobin, 35 per cent.; colour-index, 0·67; leucocytes, 6240 per c.mm.; polynuclear neutrophils, 61 per cent.; small lymphocytes, 20 per cent.; large lymphocytes, 1·5 per cent.; large hyaline cells, 7·5 per cent. Poikilocytosis and anisocytosis were present.

Two days later the boy complained of a headache which was still present on August 2nd. The pulse-rate gradually rose from 100 on July 29th to 120–128 on July 31st, and then remained between 112 and 120. A large stool containing blood was passed, and on August 3rd a blood count showed: erythrocytes, 1,300,000 per c.mm.; hæmoglobin, 20 per cent.; colour index, 0·8. A transfusion of 17 oz. of blood was given, with immediate improvement in the patient's condition. The improvement was maintained, although he passed about 10 oz. of tar-like blood.

On August 7th he complained of not being able to see properly, and screwed up his eyes. On examination there was loss of the lower half of the left visual field. The liver was not palpable. The chest and central nervous system were clear. Ophthalmoscopic examination showed papillœdema with yellowish patches in both fundi. A blood count on the same day showed: erythrocytes, 2,200,000 per c.mm.; hæmoglobin, 33 per cent.; colour-index, 0·75; leucocytes, 3720 per c.mm. On August 16th a blood count showed: erythrocytes, 2,500,000 per c.mm.; hæmoglobin, 29 per cent.; colour-index, 0·58. The papillœdema was increasing and in the left eye papillœdema, hæmorrhages, and exudate were present. The macula was unaffected. In the right eye similar changes were present. A blood transfusion of 17 oz. was given, and the next day a blood count showed: erythrocytes, 2,600,000 per c.mm.; hæmoglobin, 34 per cent.; colour-index, 0·65. On August 28th papillœdema was more marked in the left eye and half a dozen small yellowish "chicken-down" patches were present just above the left disc. A blood count showed: erythrocytes, 3,400,000 per c.mm.; hæmoglobin, 42 per cent.; colour-index, 0·62; leucocytes, 5000 per c.mm.

On Sept. 9th he complained of headache, chiefly over the left eye, and an ophthalmoscopic examination of the left eye showed papillœdema and yellowish spots of exudate. The field of vision was as before—i.e., loss of the lower and outer part of the left field. A blood count showed: erythrocytes, 3,700,000 per c.mm.; hæmoglobin, 47 per cent.; colour-index, 0·64; leucocytes, 6400 per c.mm. There was a little irregular fever the whole time he was in hospital and the pulse remained between 80 and 90. The urine contained a trace of albumin and there was a deposit of a few leucocytes, epithelial cells, and uric acid crystals.

Previously he had always enjoyed excellent health and a good appetite, and had not suffered from indigestion or diarrhœa. He had had diphtheria. He smoked about five to ten cigarettes a week. He had taken no medicine of any description before admission to hospital. Several members of the family suffer from severe epistaxis.

The patient was treated with liver juice daily and injections of collosal iron twice weekly. He was seen on Sept. 22nd, 1930. He had been in good health except for occasional attacks of neuralgic pain over the occipital region which lasted for about 48 hours. The first attack occurred about ten days after he lost the sight of his left eye. As far as he could tell, his vision had neither improved nor deteriorated. An examination of the central nervous system showed no abnormality, except that the left pupil was slightly larger than the right. Both fundi showed secondary optic atrophy, more marked in the left eye than in the right. A perimetric examination showed loss of the lower half of the left field, with marked constriction of the upper half, most marked in the outer quadrant. The right visual field was full, except for some loss of the nasal portion of the field. A blood count showed: erythrocytes, 5,800,000 per c.mm.; hæmoglobin, 92 per cent.; colour-index, 0·87; leucocytes, 5200.

Blindness hardly ever follows immediately on the hæmorrhage but usually comes on two to three days later, though never at a greater interval than three weeks (Terson[2]). The source of the hæmorrhage is varied, about 70 per cent. being from the uterus or gastro-intestinal tract. Blindness extremely rarely results from traumatic hæmorrhage. Goulden, Whiting, and Foster Moore[3] saw no case in the late war, although one case was reported by Terrien[4] in a soldier with gas gangrene. He suggests that the ganglion cells by a previous toxæmia have been rendered incapable of surviving a serious loss of blood.

Zentmayer[5] found that in 88 per cent. of cases both eyes are affected, and that in these bilateral cases 59 per cent. are totally blind. The commonest visual field defect is a loss of the lower part (23 per cent.) or a peripheral constriction (21 per cent.), marked contraction of the nasal field being rare (3·7 per cent.).

---

* Being part of a thesis written for the degree of M.B. at the University of Cambridge.

The most rational line of treatment would seem to be a blood transfusion, and Darrier[6] recommends transfusion, massage to decrease the intra-ocular tension, and in some cases paracentesis.

The ophthalmoscopic observations in these two cases were made by Mr. Charles Goulden, senior ophthalmic surgeon to the hospital, to whom my thanks are due for permission to publish the results. I also wish to express my thanks to Mr. Robert Milne for permission to publish Case 1 and to Prof. Arthur Ellis for Case 2.

ARTIFICIAL PNEUMOTHORAX.

SOME RESULTS OF OUT-PATIENT TREATMENT.

By V. S. Hodson, M.D. Oxf., F.R.C.P. Lond.,
PHYSICIAN TO OUT-PATIENTS, VICTORIA PARK CHEST HOSPITAL;
AND
R. S. Johnson, M.D., M.R.C.P. Lond.,
MEDICAL REGISTRAR, VICTORIA PARK CHEST HOSPITAL, AND CASUALTY PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

The following report deals with 26 cases of pulmonary tuberculosis treated by artificial pneumothorax during 1930 at the City of London Hospital for Diseases of the Chest, Victoria Park. The cases came, in the first instance, from sources other than the hospital itself, and the treatment was therefore a continuation of the artificial pneumothoraces instituted elsewhere. Patients only recently attending have not been included in this series. The smallness of the number does not, of course, permit of any far-reaching conclusions, but the progress of the patients seems to us to justify publication and to emphasise once more the great value of artificial pneumothorax as an adjunct to treatment in suitably chosen cases of pulmonary tuberculosis.

In taking charge of cases of artificial pneumothorax, it very soon becomes clear that the mechanical refill is only a small part of the duty involved. Each visit calls for a careful survey for changes of any kind, in symptoms, weight, temperature, or physical signs, and for consideration of the latter in conjunction with X ray findings. Frequent screening and photographs, as may be deemed necessary—preferably at not more than three-monthly intervals—are essential for keeping pace with the progress of the case and controlling the degree of collapse, especially if effusion occurs. Sputum, when present, must be recorded and examined at intervals for tubercle bacilli, and final pressures, length of intervals between refills, and the continuance of the treatment must be constantly revised.

Family history of phthisis was definite in nine cases, but negative or unknown in 17. This is not surprising, considering that patients refer only to very close relations and have, as a rule, no knowledge of other possible sources of infection during childhood.

Progress and prognosis.—Sixteen are doing well, five are doubtful (of these one is fit for work while four have a poor prognosis), and one has died. Seventeen are fit to work as against eight who are not. Special attention is drawn to these figures, which seem to us to justify a degree of optimism which could not previously have been entertained. In the majority of the cases the original occupation has been resumed. Eighteen cases have no tubercle bacilli in the sputum, while eight retain them.

Pleural effusion occurred in ten cases, in eight being serous and in two purulent; in both the latter the effusion contained large numbers of tubercle bacilli. The occurrence of a serous effusion, though calling for added care and scrutiny, does not greatly increase the difficulties of the case or adversely affect the prognosis. Purulent effusions, on the other hand, are always serious complications and involve the admission of the patient to hospital for appropriate special treatment.

Twelve cases were admitted to the wards of the hospital for special causes, of which the treatment of adhesions was the chief. Pleural adhesions are a definite handicap in pneumothorax treatment, and if accessible and suitable for division should be dealt with by thoracoscopy and electrical cautery whenever their presence is preventing a satisfactory functional collapse of the diseased lung.

The following is the analysis of our 26 cases.

Total cases, 26: male, 12; female, 14.
Family history: positive, 9; negative or not known, 17.
Lung involved: right A.P., 12; left A.P., 13; bilateral A.P., 1.
Prognosis: doing well, 16; doubtful, 5; poor, 4; died, 1.
Working or fit to work: 17.
Unfit to work: 8.
Weight: gain, 11; stationary, 8; lost, 7.
Sputum: positive, 8; negative, 18.
Condition of other lung: healthy, 17; diseased, 9.
Effusions: serous, 8 (in one case air replaced three times); purulent, 2.
Adhesions: operated on, 7; not operated on, 12.
Admitted to hospital or sanatorium: 12.
Pneumothorax discontinued: 6.
Average duration to end of 1930: 27 months.
Intervals: 1 week, 1; 2 weeks, 9; 3 weeks, 12; 4 weeks, 2; 5 weeks, 2.

In justification of our cheerful prognosis, we point to the fact that 16 patients are entirely free from malaise; sputum is either absent or free from tubercle bacilli; the second lung is healthy; the weight is steady or increasing, and all are either at work or trying to get regular employment, which is itself an additional factor in maintaining and improving mental and physical well-being.

Queen's Institute of District Nursing.—According to the report for 1930, during the last 20 years the number of nurses working in connexion with the institute has more than doubled, and the total number of nurses now working in England, Scotland, Ireland, and Wales is nearly 7000. The number of nursing associations affiliated to the institute is 1503. Each year the nurses attend approximately 680,000 cases and pay 16,320,000 visits. Under the National Gardens Scheme 901 gardens were last year opened to the public, and the £10,119 thus raised was an increase of £2354. The Queen's Institute is now to receive 40 and the nursing associations 60 per cent. of the proceeds of the garden scheme.

National Hospital for Diseases of the Nervous System.—The board hope that sufficient benefactions will shortly be received to justify the issue of an appeal for £75,000 to clear the cost of the proposed new pathological department, surgical ward, and home for male nurses. Last year the total number of in-patients was 1541, and the cost of maintenance £41,912, an increase of more than £1400; the expenditure exceeded the income by £6155. The average weekly cost per occupied bed at the hospital was £3 7*s.* 11*d.*, and at the convalescent home £1 18*s.* 2*d.* In the medical school there were last year 394 men and women students. Applicants for training in the school of massage are so numerous that the commencing classes of the course are often filled six or even twelve months before the opening of the term.

MEDICAL SOCIETIES

CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

GLASGOW, APRIL 22ND–24TH.

THE eighth British Congress of Obstetrics and Gynæcology was opened in the Lister Memorial Hall, Royal Infirmary, Glasgow, on April 22nd, under the presidency of Dr. DAVID SHANNON. After welcoming the delegates the President called upon Prof. BLAIR BELL (Liverpool) to open a discussion on the

Clinical and Pathological Features of Ovarian Tumours (Excluding Endometriomata).

After referring to the untimely death of Prof. John H. Teacher, who was to have taken part in this discussion, Prof. Bell said that, as it was impossible for him to cover the whole ground, he would deal with those parts of the subject of which our knowledge was imperfect or absent. Existing classifications of neoplasms, he said, were founded on histological, embryological, or regional bases; for ovarian neoplasms this was not entirely satisfactory. A perfect classification should be one that could be used as the starting-point of any comprehensive survey. First a distinction must be made between tumours of intrinsic and those of extrinsic origin. The former of course comprised the largest group, and consisted of neoplasms which arose from the normal integral tissues of the ovary. These tissues might be subdivided into those which are essential to the function of the ovary and those which consist of developmental relics. The extrinsic group contained new growths having their origin in developmental inclusions, invasions from without, malignant extensions, and metastases. This classification, which he gave in detail, did not, he said, illustrate the development of malignancy in a previously innocent neoplasm—a phenomenon well known, especially in connexion with lepidic new growths. The word "lepidic" was Adami's term for tumours consisting of epithelial, mesothelial, or hypothelial elements; it was, he remarked, convenient and scientifically accurate. He went on to discuss the relative frequency of the different neoplasms of the ovary. Macroscopical appearances were of importance to the operator who often had to decide on inspection whether a tumour was innocent or malignant.

Prof. Bell then dealt with some of the rarer intrinsic neoplasms, innocent and malignant. Folliculomata, he said, were of exceptional interest at the present time. He did not believe that ova were formed anew in this growth, but agreed with R. Meyer that the ovule-like areas were small lacunæ of liquor folliculi, produced by the granulosa cells of which the tumour consists. It was interesting to surmise on the evidence of uterine hypertrophy and bleeding that œstrin may be formed in excess by granulosa-cell neoplasms (folliculomata). He discussed at length so-called border-line papillary neoplasm; for himself he held that there was no such thing. Papillary tumours were either innocent, although they might give rise to local implantation (which was not a malignant phenomenon), or they were malignant. The phenomena that led to doubt were due to such conditions as "compaction" of the papillæ and to malignancy developing in small areas of the growth. Careful examination of a number of sections enabled a decision to be reached. Malignant neoplasms other than those mentioned were either: (*a*) primary tumours of intrinsic origin; carcinoma, sarcoma, or mixed; (*b*) primary malignant neoplasms arising in tissues of innocent neoplasms—namely, in cystadenomata, papillary cysts or dermoids; (*c*) secondary neoplasms of extrinsic origin, the result of metastasis; (*d*) secondary neoplasms of the ovaries by direct invasion. Grafted ovarian neoplasms in the ovary of the rabbit were shown. Examinations had been made of the fluid from the various types of cysts. No new observations were recorded, but much of interest had been noted, especially the fact that malignant cysts may contain mucin instead of pseudomucin.

Turning to clinical considerations Prof. Bell said that the relation of age, parity, and other points in the histories of the patients, and also the frequency of unilateral and bilateral neoplasms were worthy of note. In *diagnosis* difficulty arose most commonly in respect of bilateral tumours of a solid or papillary nature, especially as free fluid was often associated with both the innocent and malignant. The points to be considered were: the presence or absence of a primary malignant growth, masses in the liver, occurrence of adhesions, age, and general condition of the patient. Ascites depended on whether the tumour was sufficiently free and out of the pelvis to irritate the peritoneum, or whether there were implantations in the general peritoneal cavity. Cases were quoted to illustrate the many difficulties and pitfalls that may be encountered. The only *treatment* considered was surgical. Innocent tumours required removal, but an effort should always be made to conserve some normal ovarian tissue. In malignant ovarian disease X rays and radium appeared to do more harm than good. Chemotherapy with lead might be very useful, but in these circumstances it was usually combined with surgery. If the tumour rose above the pelvic brim laparotomy was advised by Prof. Bell, but attention was drawn to the advantage of the vaginal route, during pregnancy, for removing cysts in the true pelvis. Long incisions were favoured for the larger cystadenoma in people of middle age, owing to the possibility of malignant disease and adhesions, which were more easily separated if the cyst was untapped. The danger of adhesions to malignant neoplasms was worthy of attention. It was essential to remove both adnexa and fundus uteri in all doubtful and malignant cases even if the growth appeared localised to one side; this procedure should be practised in every case after the menopause.

Prof. Bell's remarks were illustrated by many lantern slides.

CLINICAL ASPECT.

Prof. BECKWITH WHITEHOUSE (Birmingham) said that during the last 25 years British gynæcologists had made several important contributions to our clinical knowledge of ovarian neoplasms; he quoted from A. Donald, Munro Kerr, J. W. Bride, and Green-Armytage. The operations narrated in the various papers together with the speaker's own 200 made a total of 1349. He analysed his 200 cases on the basis of Bride's investigations of a series of 100 similar neoplasms published in 1930. He grouped the results into eight tables showing the pathological type of neoplasm, age-incidence, fertility, symptoms (benign neoplasms), symptoms (malignant neoplasms), mortality of operations, surgical treatment employed, and finally the complications. Little was to be learned, he said, of the nature of tumours by correlating the symptoms and physical signs; from the practical point of view the most useful classification was the simple division into benign and malignant types. The average age-incidence was 42, the youngest 16, the oldest 74. Seventy per cent. of the material came from the age-group 30–60 years. He drew attention to the higher rate of mortality attaching to operations for ovarian tumours as compared with hysterectomy for fibroids, and pointed out possible causes for the difference, among which were the separation of adhesions with the large raw surface exposed, and the greater risk of opening the bowel and infecting the peritoneum. Reviewing the various forms of treatment, he emphasised the value of oöphorectomy in advanced malignant disease of the ovary. He had two cases alive now that had been treated with colloidal lead after double oöphorectomy, and in whom at the time of operation the prognosis appeared quite hopeless.

PATHOLOGICAL ASPECT.

Mr. T. G. **Stevens** (London) remarked that germinal epithelium is in no sense true epithelium and therefore an unlikely source of these tumours. He suggested the origin of epithelial neoplasms from traces of the primitive tubular ovary, pseudomucin being the normal secretion of this persisting tubular system. He did not believe that folliculoma or granulosa-cell cancer existed; the new formation of ova described by continental writers seemed to him contrary to all physiological and developmental principles. Ova are present in the ovaries at birth and no new ones are ever formed. Mr. Stevens considered that all these tumours were endotheliomata which might exist as benign or malignant neoplasms. He thought that innocent tumours of the ovaries never became malignant. In conclusion, he described the pathological changes which follow upon torsion, infection, and rupture of ovarian cysts, stating that when a pseudomucinous cyst ruptures it always leads to pseudomyxoma peritonei.

SURVEY OF CASES.

Mr. C. D. **Lochrane** (Derbyshire) read a paper by Mr. G. F. **Keatinge** (Derbyshire) and himself, surveying 180 consecutive cases of ovarian neoplasm. He classified these tumours into solid and cystic, further subdividing the latter into unilocular or multilocular cystadenomata and cystic teratoma. The solid are classified as innocent, malignant, or doubtful. Ascites was present in 73 per cent. of all the patients who had solid and semi-solid growths, in 28 per cent. of the benign solid tumours, and in 14 per cent. of the cystadenomata. Torsion of the pedicle occurred in 10 per cent. of all tumours. He considered the incidence of adhesions, of hæmorrhage in the tumours, of the occurrence of suppuration, and of the association of pregnancy. He described several interesting cases and a follow-up of the cases of solid and cystic malignant tumours which had been submitted to radical extirpation.

Dr. S. J. **Cameron** (Glasgow) analysed 150 cases of cancer and 19 cases of sarcoma in relation to age-incidence, presence of pain, abdominal swelling, loss of weight, period of ill-health, occurrence of uterine hæmorrhage, digestive disturbances, difficulty in defæcation, dyspnœa, vaginal discharge, pigmentation, ascites, adhesions, secondary growths, pelvic infection, rupture of the cyst and torsion of the pedicle, pyrexia, phlebitis, glandular involvement, absence of symptoms, removal of the tumour, and parity. He advocated removal of malignant ovarian neoplasms whenever possible even though the growth was advanced and clinically inoperable, as this often gave the patient a much more comfortable end. Referring to expectation of life, he had found that young patients and the old succumbed more quickly than women in middle life. He described a clinical picture which he thought should clinch the diagnosis of malignancy when this was in doubt.

Sir **Ewen J. Maclean** (Cardiff) was in the chair during the afternoon session when Dr. D. **McIntyre** (Glasgow) read a paper dealing with malignancy in ovarian tumours. He analysed 160 cases, all of whom had a reliable history and a microscopic section; 63 were malignant and 81 benign, the rest being doubtful. The relationship of age, marriage, parity, and other factors of the malignant tumours were compared with those of the benign growths. Tables were shown giving the follow-up records after five years (average) in 123 available cases, these results being examined alongside tumour types. He discussed the difficulty of classifying ovarian tumours and in arriving at a decision regarding malignancy in a proportion of cases with lantern slide illustrations. Sections of three granulosa-cell tumours were shown, with the effect of these neoplasms upon the endometrium; also a case of suspected luteinoma. Bilateral tumours were, he said, more frequent in multiparæ.

Dr. J. **Gardner** (Glasgow) read a paper on the clinical features of benign ovarian tumours, his material consisting of 300 innocent neoplasms. Many of his findings were in agreement with what had been said by previous speakers. While it was true that the uncomplicated ovarian tumour might be symptomless, he had found symptoms in a great majority. In 40 per cent. of the cases there were complications of some moment; of these, torsion was the most frequent, not confined to tumours of moderate dimensions. Menstrual disturbances were not of sufficient uniformity or frequency to have any significance. Solid tumours constituted 4 per cent. of the total.

DISCUSSION.

Prof. H. **Guggisberg** (Berne) discussed the pathogenesis of ovarian tumours. Folliculomata he held to arise from Graafian follicle epithelium. In two cases he had seen the uterus was enlarged to twice the normal size, but returned to normal when the tumours were extirpated. With reference to secondary carcinoma, he felt sure that malignant change could occur in pre-existing innocent tumours. Clinical signs were much to be relied upon. He had also experienced the high operative mortality described by other speakers and attributed it to the fact that many of the patients in Switzerland did not seek treatment until their tumours had reached an enormous size. He advocated the use of X rays for the treatment of ovarian tumours of certain types.

Prof. **Munro Kerr** (Glasgow) referred mainly to the surgery of ovarian tumours. The relatively high mortality of ovariotomy as compared with hysterectomy was outstanding. He thought that the uterus should always be removed if malignancy was suspected. In a difficult case the operation should be commenced on the easy side and then the more difficult could be approached from below; in this way damage to the ureter was often avoided.

Prof. **Louise McIlroy** (London) referred to the developmental anatomy. She did not think that ova could be developed anew in malignant tumours. She thought also that many of the solid ovarian tumours were endotheliomata. Whenever it was possible she advocated leaving a portion of ovary in situ. She could not help feeling that there must be some more intimate connexion between the breast and the ovaries than merely that of the lymphatics or blood stream to account for their frequent involvement by secondary growths.

Prof. R. J. JOHNSTONE (Belfast) said he had seen ovarian cysts rupture as the result of violence. He referred to two patients in whom torsion of the pedicle of an ovarian tumour had completely separated the neoplasm from its attachments. He considered that multilocular ovarian tumours might have an effect on menstruation such as prolonging the onset of the menopause and even causing menorrhagia. His operation results showed six deaths out of 130 ovariotomies. The fact that one of his patients died as soon as he had eventrated a large tumour made him lean towards puncturing all cysts in patients with feeble circulations to prevent shock.

Prof. GREEN-ARMYTAGE (India) said that in his practice the high operative mortality was due to the large size of the cysts dealt with. His series also showed a large number of broad ligament cysts. In a number of the cases it had been necessary to remove both ovaries and the uterus for broad ligament cysts.

Dr. LEITH MURRAY (Liverpool) agreed with Mr. Stevens as regards ovarian carcinoma not developing in innocent neoplasms. He believed that pseudomucinous and also papillomatous cysts remained innocent. He referred to recurrence after operations, rupture of cysts, and the incidence of suppuration of which he had only seen one case.

Dr. CANTOR (Pennsylvania) referred to granulosa-cell tumours, quoting the work of Robert Meyer. These tumours were very seldom bilateral; the symptoms disappeared upon removal of the tumours with a return to normal of the uterus. Out of a series of 33 cases collected by Meyer 19 were alive and well over three years after operation.

Dr. BETHEL SOLOMONS (Dublin) wished to obtain information about the treatment of residual portions of ovarian carcinoma following surgical intervention. He had utilised several methods but had not met with much success. X rays, he thought, were detrimental. Pseudomyxoma peritonei he considered malignant.

REPLY.

Mr. STEVENS said he did not agree that hysterectomy was necessary with bilateral ovarian tumours if the uterus was normal, as recurrence never occurred in this situation.

Prof. WHITEHOUSE said he had utilised various forms of treatment for residual masses and recurrence after incomplete operations for malignant ovaries. Radium and X rays were disappointing.

Prof. BELL pointed out the possibility of differentiating between bilateral ovarian fibromata and sarcoma at operation. Referring to Prof. Whitehouse's remarks, he said he had never experienced difficulty in resecting portions of ovary. With regard to the operation mortality-rate he was a believer in spinal anæsthesia for weakly and elderly subjects. As to the question of the route whereby secondary tumours reached the ovaries from primary gastric and mammary carcinoma, he remarked that in transplantable carcinoma of the rabbit it had been found that the growth proceeded to the lowest part—i.e., the diaphragm. Mr. Stevens, he added, had produced no pathological material to substantiate his statements; he (the speaker) had satisfied himself that malignant change occurred in innocent neoplasms. He recognised the essential differences between folliculomata and endotheliomata of the ovary.

Teaching of Obstetrics.

On the second day Dr. H. S. DAVIDSON (Edinburgh) was in the chair during the morning session, when the President read Prof. S. A. GAMMELTOFT's paper on the teaching of obstetrics and gynæcology, and the methods employed in Copenhagen. He dealt with maternal mortality and the desire to reduce the infantile death-rate. In the past antenatal care had been regarded as the way to combat maternal and child mortality. Now improved instruction of students in midwifery seemed to be the keynote. The medical course which extended over seven and a half years in the University of Copenhagen was outlined. He did not set much importance on theoretical lectures but believed rather in giving the students practical demonstrations; most of their time should be spent with patients; discussions between students and teachers were valuable. Puerperal care of the mother and child were demonstrated practically in the wards by the nursing staff. One of the deficiencies of his school was that attendance at antenatal clinics was not compulsory. On qualifying the student must take a practical obstetrical course for one month before he was allowed to attend labour cases. The post-graduate teaching was conducted by Prof. Gammeltoft and his assistants, the chief midwife also taking an active part in supervising the work. Abdominal examination was mostly utilised. Finally, the accommodation for deliveries and operative treatment was discussed.

DISCUSSION.

Prof. GUGGISBERG outlined the curriculum of his school where most time was given up to the teaching of midwifery, as Swiss practitioners, owing to transport difficulties, had to deal with all emergencies as they arose. Great stress should be laid on the biology and pathology of pregnancy and the puerperium. He was a strong exponent of rectal examination.

Prof. WHITEHOUSE considered that in this country too much time was given to the teaching of gynæcology. He agreed with Prof. Gammeltoft's remarks as to the ideal to be aimed at. He now employed films to illustrate abnormalities of labour to his students.

Dr. J. S. FAIRBAIRN (London) agreed with the previous speakers but pointed out that every teacher had his own methods. He believed that students should for a time live in an atmosphere of obstetrics. He supported those who utilised their midwives as teachers. He taught non-interference, and the desirability of encouraging physiology to take its course.

Prof. KERR said that there was no minor surgery in obstetrics. Antenatal care was being well taught, but intranatal methods were more essential and should be emphasised. He discussed the ways and means of carrying this out.

Mr. L. C. RIVETT (London) said it was a waste of time for students to be watching operations and suggested that they spent far too much time doing surgical dressing. He disagreed with rectal examinations and emphasised postnatal care.

Dr. SOLOMONS felt that a whole-time professor teaching in the university and also in the clinic was what was most desirable. Residence in an obstetric hospital for a sufficient period should be the keynote of the teaching of midwifery. It was a knowledge of the physiology of labour that was important. A certain number of cases should be conducted personally by the student, but more important still was that each man should see a large number of cases and actually write them up. He had become a complete convert to rectal examinations.

Prof. JOHNSTONE thought that practical experience of midwifery should be increased so that the student developed an obstetric conscience.

Dr. G. FITZGIBBON (Dublin) said that midwifery should be brought into line with the teaching of medicine and surgery.

Prof. BELL was surprised that none of the previous speakers had referred to infant welfare. He was convinced that the surest way to combat maternal mortality and disablement was to commence with the neonatal period and bring up healthy mothers. If such diseases as rickets and heart disease were prevented in children many obstetrical complications would be avoided later.

Dr. W. H. F. OXLEY (London) said he was taught obstetrics by whole-time midwives and felt that this was a useful way of gaining experience. He was speaking as an obstetrician and not as a teacher.

Prof. M. PHILLIPS (Sheffield) said that students should be saturated with normal obstetrics and not taught operative midwifery. He felt that by watching gynæcological operations during their obstetric course students were being taught preventive gynæcology.

Low Back Pain in Gynæcological Practice.

Dr. JAMES YOUNG (Edinburgh) said that low backache was one of the commonest symptoms in patients referred to the gynæcologist. In many of these cases the pain was dependent upon orthopædic conditions, and unless these were recognised the operative treatment of such associated conditions as vaginal prolapse and retroflexion was followed by disappointment. The cause could be ascribed to inherent weakness and in some cases to excessive strain during childbirth, but most often it was due to faulty posture dating from pregnancy or developing secondarily after damage of the pelvic floor and the production of prolapse.

Mr. W. A. COCHRANE (Edinburgh) drew attention to the mechanism of production and the pathology of the condition, illustrating his points by means of lantern slides and diagrams. He said that the symptoms were referable to disease of the lower spinal and sacral joints. Special orthopædic examination and careful scrutiny of good X ray pictures were important aids to diagnosis. Many women used their bodies in positions of mechanical disadvantage; the pelvic organs were not responsible for the pain and spasm of the back muscles was often found. He classified the cases into: (1) traumatic strain causing torn muscles and ligaments; (2) lumbosacral strain found most commonly in fat women; (3) sacro-iliac strain found in slender women; (4) combined pelvic joint strain; and (5) general postural cases. He summarised the diagnosis and treatment.

DISCUSSION.

Dr. R. S. S. STATHAM (Bristol) agreed with the importance of the conditions described, and said he had treated 41 cases with good results by means of massage and exercises. Sacralisation of the last lumbar vertebra had been found to occur in about a twelfth of the population. He referred with appreciation to Guy Hunner's work on ureteral strictures.

Mr. EARDLEY HOLLAND (London) said that backache in women had persisted as a traditionally gynæcological disease, but cases never really occurred in whom it could be directly ascribed to the pelvic organs. Pregnancy and labour were, however, common causes of sacro-iliac strain. He quoted the history of a case relieved of intractable backache by having her sacro-iliac joints fixed by means of a tibial graft.

Radiotherapy and Fistula Formation.

Dr. G. I. STRACHAN (Cardiff) discussed the frequency and method of occurrence of fistula formation in cervical carcinoma, the part played by radiotherapy, and the prevention of this complication. In a series of 254 cases fistulæ had developed in 22—viz., ten vesico-vaginal, nine recto-vaginal, and three recto-vesico-vaginal. The time of appearance of these fistulæ after radiation and the duration of life were discussed. No early cases developed fistulæ. He pointed out that the technique of radium application was the same in the cases where no fistulæ developed. All the cases were advanced, and in all except two there was an interval of several months between radiation and the appearance of the fistula, so that the radium probably had little influence on its formation. The points emphasised were bowel and bladder evacuation, with vaginal packing.

DISCUSSION.

Dr. CAMERON said he had employed the Stockholm technique extensively in the treatment of cancer of the cervix, having completely given up the Wertheim operation. He described in detail his methods, dosage, and results. He was giving radium a good try out in these cases, and if it did not prove satisfactory he would next resort to vaginal hysterectomy.

Mr. M. DONALDSON (London) divided fistulæ into those which were the result of radium and those which were due to the growth. He had not seen vesico-vaginal fistulæ but had found several between the rectum and vagina. He described his method of dealing with the latter. He did not agree that we knew which treatment was more likely to cause fistulæ.

Ovarian Grafting.

Dr. SOLOMONS read a paper on ovarian grafting from one woman to another. He reviewed the literature of auto- and hetero-ovarian grafting, dealing with the suitability of donors, indications, technique, and results, also with the possibility of pregnancy following grafting. He described in detail the methods employed in grafting a portion of the ovary taken from a healthy girl into the rectus muscle of a woman in whom an artificial menopause had been brought about by means of radium and who was anxious to menstruate again. The operation was successful and brought about the desired effect.

No time was left for discussion, and those desirous of commenting upon the paper were invited to contribute their remarks in the *Journal of Obstetrics and Gynæcology of the British Empire.*

Shorter Papers.

During the afternoon session Prof. A. H. DAVIDSON (Dublin) was in the chair, and Prof. GUGGISBERG read a paper on

CONDITIONS OF LIFE AND REPRODUCTION.

He divided life into: (1) intra-uterine with its ties to ancestors and parents; and (2) extra-uterine. The development of the child is uninfluenced by the mother's nutrition during its intra-uterine existence. The blood composition is constant, the placental metabolism cannot be influenced except by very extreme degrees of starvation which could only be brought about in experimental animals, conditions unlikely to be reproduced in human beings. The placenta is quite passive to an over supply; it merely picks out what is necessary from what is offered. His own experiments had shown that the placenta has a great vitamin storage capacity. A pregnant animal fed with antirachitic substances would produce young upon which the most extreme rachitic diet would have no effect. The fœtus receives, he said, a certain amount of protective factor from the mother which protects it after birth. He referred to the effect of civilisation upon fertility and the influence of nutrition, light, and meteorological conditions on the germ glands. Stress was laid on the fact that the sexual fitness of a woman is determined to a great extent before and during puberty.

Prof. **Whitehouse** referred to external influences causing death of the ovum in utero. He pointed out that if women who repeatedly aborted were given vitamin E whilst pregnant they might go to term. He had found that if a last child of a large family married an individual who was also the last child of a large family frequent abortions were more likely to occur.

THE HUNTERIAN COLLECTION.

Prof. J. H. **Bryce** (Glasgow) demonstrated the Hunterian collection of anatomical and pathological preparations at the University of Glasgow, drawing special attention to early embryos, injected preparations of decidua and placenta, and preparations to illustrate the comparative anatomy of the placenta. He also showed specimens illustrating injection of the lymphatics by means of mercury and Hunter's casts made from the preparations which were used for the drawings in his work on the gravid uterus.

INDUCTION OF LABOUR.

On the last day Dr. **Statham** took the chair and Dr. **FitzGibbon** read a paper on the induction of labour by puncture of the membranes. There was no case, he said, in which labour failed to follow by this method and it was free from any of the so-called disadvantages from loss of the liquor amnii. The method is applicable to all cases in the last six or eight weeks of pregnancy, and he held that it more nearly promotes the normal stimulation of uterine action than any other method. The primigravida showed a more rapid response to the induction than the multigravida, but in both groups labour was steady and rapid when it started. As much liquor as would make the presenting part press firmly on to the internal os should be allowed to run away. The best results were obtained by puncturing the membranes in front of the presenting part.

BLOOD EXTRAVASATION AND ALBUMINURIA.

Dr. **O'Donel Browne** (Dublin) said he had found as a result of clinical observations that there was an intimate relationship between blood extravasation and albuminuria. Even when only a small quantity of blood was extravasated, albuminuria developed if the blood was locked up. It was seen in ectopic pregnancy, post-operative hæmatomata in the non-pregnant, and in cases of traumatic hæmatoma. The albumin cleared up in all cases after the removal of the clot. Details of cases were given to illustrate that even small blood extravasations were capable of producing albuminuria.

UPPER URINARY TRACT IN PREGNANCY.

Dr. **Dugald Baird** (Glasgow) said that pyelitis of pregnancy was much more common than generally supposed, being predisposed to by the dilatation of urinary tract which occurred during pregnancy. That the ureters become dilated very early in pregnancy was shown by post-mortem findings, by dye excretion, and by pyelography. It was usually more marked on the right side. This dilatation has a deleterious effect on kidney function, causing delay in excretion and diminution of the power of the kidney to concentrate urea. In infected cases the dilatation and delay in excretion was greater, and in these cases he advised drainage of the pelvis by a catheter.

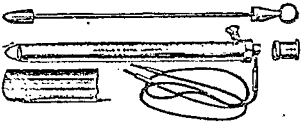
TRANSPLACENTAL MELANOTIC SARCOMA.

Mr. **Holland** reported a case of transplacental implantation of melanotic sarcoma from mother to fœtus. The patient had had a growth removed from the skin of the thigh and a recurrence which was also excised with the femoral and inguinal glands. Two months later she became pregnant and when seen near term was extremely ill with nodules in the skin all over the body. The lower uterine segment was occupied by a large soft mass which was presumed to be the placenta. Cæsarean section revealed a black placenta prævia. The child was apparently healthy. The mother died three months later. The child died when 8 months old and at post mortem its liver was found to be greatly enlarged by nodules of melanotic growth. Specimens and drawings were shown to prove that the tumour must have passed from the mother to fœtus by the placenta.

NEW INVENTIONS

A MODIFIED SIGMOIDOSCOPE.

I have devised a modification of the Lockhart-Mummery sigmoidoscope. The lamp, instead of being on a long stem, inside the lumen of the instrument, is recessed in its walls, and protected by a window which is situated a short distance from the distal end. The advantages of this arrangement are that the lamp and holder cannot be fouled by fæces, nor can the swabs be caught in the lamp. When the lumen of the sigmoidoscope does become soiled, the one action of cleaning the instrument also cleans the window behind which the lamp is recessed and protected. I have also had a rectal speculum made on the same principle.



The makers are John Bell and Croyden (Arnold and Sons), 50–52, Wigmore-street, London, W.

Frank Harvey, F.R.C.S. Edin.

Braintree and Bocking Cottage Hospital.—This Essex institution is to be re-named "The William Julien Courtauld Hospital" in recognition of the liberality of its donor and president.

Paddington Children's Hospital.—Last year 794 in-patients were treated at this hospital (a fractional decrease) at a weekly cost of £3 17*s.* 10*d.* and a total cost of £8 3*s.* 6*d.* each; their average stay was 14·77 days. Out-patients, who made 42,201 attendances, cost 7*s.* 9·8*d.* each. Voluntary payments from patients were £707, a heavy decrease; on the other hand, the Hospital Saving Association's payment of £1097 was an increase of £126. The convalescent home is to be moved from Slough which, as a big industrial town, is no longer suitable for the purpose, to a house on Bagshot Heath.

REVIEWS AND NOTICES OF BOOKS

Bronchial Asthma, its Diagnosis and Treatment.

By HARRY L. ALEXANDER, A.B., M.D., Associate Professor of Medicine, Washington University Medical School, St. Louis, Mo. London: Baillière, Tindall and Cox. Pp. 171. 10*s.* 6*d.*

Asthma and its Treatment.

By PERCY HALL, M.R.C.S. Eng., L.R.C.P. Lond., late Hon. Actinotherapist, Mount Vernon Hospital, London and Northwood. London: William Heinemann, Ltd. Pp. 130. 7*s.* 6*d.*

The Treatment of Asthma.

By A. H. DOUTHWAITE, M.D., F.R.C.P. Lond., Assistant Physician, Guy's Hospital. London: H. K. Lewis and Co., Ltd. 1930. Pp. 164. 7*s.* 6*d.*

AUTHORS of monographs may be divided into two classes—those who by investigating a subject make an original contribution to human knowledge and then write a book after a careful study of all the earlier published work. It is needless to say that such special investigations may be purely clinical, such as studying the effect of some new method of treatment on a series of cases, or it may be experimental so that the underlying pathology or the underlying principles of treatment are elucidated. The second class comprises those authors who claim no originality for their work, but have made a compilation of the works of others. These three books illustrate these two types of monograph.

Dr. Alexander's book is excellent, being an authoritative representation of the best work that has been carried out on the subject of asthma up to the date of its publication. Special attention should be paid to his discussion of the mechanism of the asthmatic paroxysm; it is interesting that he comes to the conclusion that bronchial spasm and mucosal œdema causing excess of mucous secretion occur simultaneously during the attack, and that they all play a part in the production of the dyspnœa. Other notable features of the book are the account of the migration of eosinophil leucocytes through the capillary walls to accumulate in the pericapillary and peribronchial tissues, and finally to penetrate into the bronchial lumen; the description of the Charcot-Leyden crystals; the acceptance of the view that the lungs are not uniformly involved during a paroxysm. Dr. Alexander has studied the size of the heart with special reference to the disputed question whether there is usually a right-sided hypertrophy, and records the measurement by radio-active methods of the blood-flow through the lungs in emphysema. His original work includes notes on the experimental investigation of the disease during life, and an account of the post-mortem examinations in three cases of asthma; and we learn that not more than 34 autopsies have been described in the literature. He found that the thickness of the bronchial wall for a certain type of bronchus is twice as great in asthma as in normal controls. The book is packed full of information of all kinds, and contains full references.

Dr. Percy Hall writes his book from the point of view of a physiotherapist. The two methods that he describes most fully are diathermy and actinotherapy, and he lays special stress on the value of the latter. Twenty-one case-histories are given at the end of the book. Dr. Hall has not attempted to deal with the history of the subject, nor to describe the various researches which have recently been conducted, and he gives no references or bibliography. We regret that the author did not confine himself to an account of those physiotherapeutic measures on which he is a known authority, and which he might have expanded further with advantage. Such excursions as he makes into the general pathology of asthma are marred by a number of statements concerning hypothyroidism, adrenal dysfunction, pituitary deficiency or abnormality, and vitamins, which are in some cases obvious, in others irrelevant to the argument. For instance, the presence of a harsh, dry skin, common in asthmatic subjects, is poor evidence that hypothyroidism is an important factor. Again, how does disorganisation of the lungs "throw a strain on other organs of excretion which have more than their share of the work to perform?" Does Dr. Hall suggest that there is ever any special excretion of carbon dioxide by the skin or kidneys? His explanation of the action of adrenalin is, to say the least, unusual. His work would have been more effective if he had confined himself to clinical description and avoided unproven theories.

Dr. Douthwaite's book is frankly a compilation. He disclaims any originality in the preface; but he might have taken credit for a good section on the treatment of asthma by means of physical exercises. He is in close touch with the work of the Asthma Research Council, and is thus able to take account of this work in his presentation of the subject. Contrary to Dr. Alexander—in this Dr. Douthwaite is surely wrong—he regards the dyspnœa as due to spasmodic contraction of the bronchi, considering that the swelling of the mucous membrane, if it plays any part at all, is of minor importance. Dr. Douthwaite draws on his own clinical experience for certain interesting cases. A useful chapter deals with the methods required for investigating a case, and describes the special tests employed. The description of anaphylaxis is poor; in a future edition an abstract of Dale and Kellaway's work should surely find a place. The introduction of the term allergism is unfortunate, or was this perhaps a printer's error? The book as a whole gives an orderly, clear, and complete account of asthma, including pathology, symptomatology, and treatment.

Abdomino-pelvic Diagnosis in Women.

By ARTHUR JOHN WALSCHEID, M.D., Director of Obstetrical and Gynecological Department of Pan-American Medical Center and Clinics, New York City. With 397 illustrations and one colour plate. London: Henry Kimpton. 1931. Pp. 1000. 52*s.* 6*d.*

THIS imposing volume is intended primarily for the post-graduate student and the general practitioner. The author has attempted to give the book "an anthropological subtratum, as an essential element in diagnosis." In place of predisposing causes of individual affections he has preferred to think of the idea of the type of patient who is predisposed to the affection in question, which he believes to give the reader a better aid to visualisation than is acquired by dealing with abstractions.

Part I., general gynæcology, opens with a chapter on anatomical considerations, but it is not the anatomy of the ordinary gynæcological text-book that the reader must expect. Instead he will find most interesting sections on such subjects as the normal female figure (profusely illustrated), *racial types*, primary and secondary sex characteristics, the influence of age on the female body and topographical visceral anatomy. In the next chapter general ætiological factors are considered and general symptomatology, and under the latter we find discussed the *types of endocrine and enteroptotic patient, anomalies of menstruation, uterine hæmorrhages, and sterility*. *Under sterility* no mention is made of the value and use of lipiodol in locating the site of tubal occlusion, and only the following obscure statement is made: "Although in theory the fluoroscope and roentgenography should be used these are unnecessary so long as the manometer functions." We conclude that the writer means "unnecessary so long as the tubes are shown to be patent" by passing air through them. But if there is an obstruction its position cannot easily be located without an injection or open operation. 113 pages are devoted to gynæcological examination and diagnosis. The length of this chapter is due to the fact that it includes such detailed directions as those for preparation and examination of frozen sections, embedding in paraffin, microscopic examination for gonococci, methods of determining amount of blood loss, the internal secretions in diagnosis, besides many other matters not usually met with in a gynæcological text-book.

In Part II., special gynæcology, the arrangement differs from that usually followed, in that in its nine chapters all the diseases and functional disturbances of each organ are discussed together. The grouping is therefore not primarily pathological but anatomical. Thus the reader who wishes to read up the diagnosis of gonorrhœa will not find it under one heading—e.g., infections of the genital tract—but distributed under vulva, vagina, and cervix. This seems to lead to much unnecessary repetition, and here and there the work would have gained by condensation into two-thirds of its bulk, especially when one considers that the bibliography (most of it German) only fills three pages. The principles of gynæcology as taught in this country at least are simple. We believe that this is because the teaching is based on the general and universal principles of pathology. If these are understood and applied, classification of symptoms and signs becomes easy; once depart from them and all becomes confused and difficult. Much of the pathological teaching in the book under review is open to objection. For example, in the section on cervicitis there is no insistence on the fact that the condition is due to infection. "Erosion results from leucorrhœa which latter may be infective or non-infective. It may result from mechanical irritation—friction against the contiguous vaginal wall. . . . It may be the result of laceration of the cervix which has caused obstruction of the ducts of the glandules of the cervix." Precisely how obstruction of the ducts of the "glandules" of the cervix causes "erosion" is left to the reader's imagination to discover! This, in our view, is bad pathology, or no pathology at all. In the section on chorion epithelioma (the term deciduoma malignum given as a synonym is obsolete) it is stated that it "grows from decidual cells." Every student knows nowadays that it grows from the chorionic epithelium. Nor is this a misprint, for farther on it is said that in lung metastasis the blood from the lungs "will be found to contain the decidual cells"! Some mention, too, might have been made in connexion with the diagnosis of chorion epithelioma of the important work of Zondek and Aschheim, Erhardt, and others on the value of the pregnancy reaction, especially as the book bears the date 1931 as the year of publication.

The reader will find much useful information in this book provided his patience does not give out in the prolonged process of extracting it. It is a work only for the experienced gynæcologist who can reject what is unsound, for without doubt there is much valuable matter. The illustrations are mostly good, some are excellent, but the microphotographs, except those taken from other works, are so poor as to be almost useless.

Recent Advances in Pulmonary Tuberculosis.

Second edition. By L. S. T. BURRELL, M.D., F.R.C.P., Senior Physician to Royal Free Hospital; Physician to Brompton Hospital for Consumption and Diseases of the Chest. London: J. and A. Churchill. 1931. With 32 plates and 17 text-figures. *Pp.* 240. *12s. 6d.*

TAKING stock of the advances made in the treatment of pulmonary tuberculosis since the first edition of his book was published, Dr. Burrell comes to the conclusion that they have been mostly along surgical lines. Hence his expansion of the chapter on thoracoplasty, extrapleural pneumolysis, and phrenic evulsion. Intercostal neurectomy, cauterisation of adhesions, and oleothorax are also discussed. Other new features of this edition are articles on poison gas and war injuries caused or aggravated by tuberculosis, and the problems raised by the combination of pregnancy with pulmonary tuberculosis. In the preface to the second edition the author states that the results of further experiments with B C G are included. This is quite true. But the account of the Lübeck disaster is very inadequate, and the general survey of the B C G literature is rather sketchy. There is another field in which the author might well have been more expansive. It is that of the X ray diagnosis of pulmonary tuberculosis, the work of Redeker and his school, and the teachings coming under the heading of "Frühinfiltrat." Dr. Burrell steers his way very sagely through the contentious paths of graduated labour and tuberculin treatment. Of the latter he remarks that while the beneficial effects of certain treatments, such as rest in bed, are plain, the benefit of tuberculin is still a matter of debate.

Hypersensibilités spécifiques dans les affections cutanées.

By PASTEUR VALLERY-RADOT and Mlle. HEIMANN. Paris: Masson et Cie. 1930. Pp. 146. Fr.25.

THE importance attributed to a specific susceptibility in the genesis of cutaneous disease has greatly increased during recent years. In urticaria, this ætiological factor, has long been accepted and most authorities are now agreed that eczema, dermatitis artificialis—which includes dermatitis due to medicaments applied or ingested—Quincke's œdema, and even the dermatitis herpetiformis of Duhring, should be grouped under the manifold symptoms of allergy. A collective survey such as this, illustrated by many brief case records, marks progress, and will be welcomed by dermatologists all over the world. The authors do not enter too deeply into the complicated considerations which underlie the experimental work performed by themselves and other investigators in France, America, and Germany. The work in this country of Cranston Low, who has contributed some important original observations, and a most valuable text-book, appears to have escaped their notice. They pass quickly to a survey of clinical data in relation to the two recognised types of cutaneous allergy—viz., the acquired, corresponding with the experimental type, and, secondly, the so-called spontaneous hypersensitivity at first contact or on ingestion, for which the term idiosyncrasy is sometimes used. In this chapter are described the blood and vascular phenomena which always precede and sometimes accompany the cutaneous manifestations, and without which, according to these authors, the diagnosis of allergy ought not to be made. The various and increasingly numerous protein and non-protein substances—the antigens—which have been found at one time or another to elicit the syndrome are enumerated in detail, with case-histories, and the following chapter contains a full account of the diagnostic means to prove their specificity.

The second part of the book examines evidence for classifying the dermatoses mentioned above as allergic in origin, and the third is a most valuable essay on treatment. The practitioner will find all that he requires about treatment in this section, since it includes the therapeutic weapons which are used when the antigen cannot be discovered. The chronic sufferer from urticaria is difficult to cure, and every physician has cases of eczema or dermatitis herpetiformis which have resisted the most drastic efforts to relieve them. In these pages will be found the latest fruits of therapeutic research.

Seasonal Variation in Man.

By Edmund Hughes, M.R.C.S., L.R.C.P. London: H. K. Lewis and Co., Ltd. 1931. Pp. 126. 6*s*.

Dr. Hughes starts with the reflection that mammalian physiology has been built on the expectation of annual inactive periods during cold weather, and thinks it possible that in a heat-stable animal such as man traces of the consecutive chemico-physiological rhythm still persist, and may become manifest under appropriate conditions. We agree with him that conventional pathology does not represent any intense conviction of the importance of our evolutionary history; it would be well to trace out the functional implications of evolution more fully. But we confess that we find Dr. Hughes's treatment unsatisfactory; he is too vague, and his speculations often overrun that indefinite line called legitimate. His readers will, we imagine, prefer to pursue his general idea along lines of their own.

Clinical Methods in Tropical Medicine.

Fourth edition. By G. T. Birdwood, M.A., M.D., D.P.H., Lieut.-Colonel, I.M.S., late Civil Surgeon, Lucknow. With Contributions by Various Authorities. Calcutta: Thacker, Spink and Co. 1930. Pp. 366. Rs.8.8.

The object of this small volume as set forth on the title-page is to act as a guide for students and general practitioners in the tropics in diagnostic and therapeutic measures, and this it does in plain and simple language. That there is much that is unscientific and misleading in these pages we are bound to admit. The description of the malaria parasites is so vague that it would be difficult even for a trained observer to differentiate between them without more help than is given here. The scope of the work is ambitious; the subjects dealt with range from methods of blood examination to the diagnosis and treatment of gonorrhœa, tests for renal function, the removal of the brain of a rabid dog, and the method of embalming a dead body being included. In the treatment of kala-azar no mention is made of the pentavalent compounds of antimony. The wisdom of including in such simple tracts as leaflets to village headmen notes on the diagnosis of relapsing fever and the Spahlinger treatment for tuberculosis is open to criticism.

Recent Advances in Physical and Inorganic Chemistry.

Sixth edition. By Alfred P. Stewart, D.Sc., Professor of Chemistry in the Queen's University of Belfast. London: Longmans, Green and Co., Ltd. 1930. Pp. 387. 18*s*.

In order to keep the work up to date the author has wisely deleted chapters from his last edition and has added new ones; this is a much wiser plan than continuously increasing the size of the work. The author in this book covers a wide range, but it is mainly devoted to molecular physics. Starting with chapters on line spectra the reader is taken through recent developments in X ray spectra, the question of radio-activity and its relation to atomic disintegration, and from there to the various emanations such as radon and thoron. The author then plunges into what to most medical and biochemical readers is a closed book, the isotopes, and the conception of the structure of the atom. The value of a book of this nature to the physicist is small, since it is too elementary for him, and the question arises whether it is sufficiently clear to enable the general reader to understand it. We find that it is written very clearly and that it is possible for a non-mathematical person to understand and enjoy the greater part of it. The author deserves congratulation on this fact and also on his general attitude. He neither patronises his readers nor attempts to thrill them by adopting a forced or dramatic style. The book will be found valuable by workers in collateral sciences such as physiology, biochemistry, bacteriology, and pathology, and should be kept in their departments for reference.

Photobiologie.

Grundlagen, Ergebnisse, Ausblicke. By Ludwig Pincussin, Dr. Med. et Phil., Direktor der Biolog.-Chemischen Abteilung am Städt. Krankenhaus am Urban zu Berlin. Leipzig: Georg Thieme. 1930. Pp. 543. M.36

The author of this work is a well-known authority who has himself contributed much to our present knowledge on light in its biological applications. This book will add to his reputation and can confidently be recommended to those who wish to review the subject. A third of the book is given up to the physics and chemistry and the remainder is concerned with the biological effects of light; this latter part is particularly clear and informative. The changes in the skin, the study of pigmentation, and the diseases which are associated with hypersensitivity to light (hydroa, eczema, solare, and so forth) are fully considered, but the author admits that attempts at desensitisation in these conditions have so far been fruitless. Of special interest to medical readers are the chapters on the action of light on micro-organisms, on toxin and antitoxin, on calcium metabolism, and on rickets.

The value of this erudite work is enhanced by full references to the literature and a good index.

THE LANCET.

LONDON: SATURDAY, MAY 9, 1931.

THE PASTEURISATION OF MILK.

Recent debates in Parliament and discussions in the press have shown that this country lags behind many others both in its consumption of milk and in the quality of the milk it consumes. As Lord Astor pointed out,[1] Canadians drink twice as much per head, Americans three times, and Danes and Swedes six times as much as we do. Our under-consumption of milk is no doubt partly due to faulty education, but both defects are certainly due to our failure to grapple with the problem of producing an adequate quantity of safe milk. In the Memorandum on "Bovine Tuberculosis in Man" issued this week by the Ministry of Health[2] the present position is summarised, the figures agreeing substantially with those given by other authorities. Although the death-rate from non-pulmonary tuberculosis in England and Wales is decreasing, the incidence is still deplorably high. The report declares it probable that more than a thousand children under 15 die of bovine tuberculosis every year. Lord Moynihan,[3] speaking in the House of Lords on Feb. 10th, quoted figures showing that over 30 per cent. of tuberculosis in children up to 15 in England is of bovine origin; and he stressed the adult morbidity, sometimes unrecognised, from this source. He quoted authority for the statement that contaminated milk is responsible for 70 per cent. of the tuberculous diseases of bones and joints, and for some 60 per cent. of enlarged tuberculous glands in the neck, while in Scotland 90 per cent. of glandular enlargement in the neck and 60 per cent. of bone and joint tuberculosis are ascribed to milk-borne infection. He pointed out that the nation lost a hundred people from and spent a quarter of a million pounds every day on tuberculosis. The Memorandum states that the proportion of milch cows in this country infected with tuberculosis is probably not less than 40 per cent.

The spread of bovine tuberculosis to the consumer of milk can theoretically be avoided in three ways: (1) by ensuring that only milk from healthy cows is marketed; (2) by ensuring that only healthy milk is sold; (3) by teaching all consumers to boil their milk as soon as it is received. The last method is obviously a measure of desperation. Lord Moynihan states that milk taken into his own house is immediately boiled and holds that its nutritive value is not diminished thereby; but it is idle to expect that all or even most of the households of the country would follow this procedure, and there is good authority for the belief that boiling impairs the calcium and phosphorus content and destroys some vitamins —indeed, Lord Moynihan admits this. His suggestion that these defects can easily be compensated may be true for well-organised and leisured households, but the need to add to her children's diet special factors which ought to be present in their natural food lays a heavy burden on the already harassed housewife and is a duty that the careless will certainly neglect. It may be argued that she should not be told to boil it but to heat it to such a degree and for such a time that the pathogenic organisms are destroyed while the food values are retained—a kind of amateur pasteurisation. The answer to this proposal is that pasteurisation is not a method which can be applied by amateurs. The Memorandum stresses the very narrow limits of temperature within which the bovine tubercle bacillus is killed while the food value is unimpaired. Strict scientific control, it states, is necessary for efficient pasteurisation. All this practically means that the housewife cannot deal adequately with the milk as delivered if she is to regard it as requiring purification; its cleanliness must in some way be ensured by the producer or the dealer. The only means by which the dealer can render milk safe without unduly spoiling it as a food is pasteurisation. This is defined in the Milk (Special Designations) Order, 1923 as the retention of milk at a temperature of not less than 145° F. and not more than 150° F. for at least half an hour, and then immediate cooling to a temperature of not more than 55° F., the milk being heated once only and not otherwise treated by heat. Pasteurisation, if performed with efficient apparatus and continually controlled by bacteriological tests, will reduce the danger from milk-borne infection to a negligible amount, but, if these conditions are lacking, the method is untrustworthy. The first method—that of ensuring the health of the herd and the cleanliness of the milker—is the ideal one, but at the present time it presents so many difficulties as to be incapable of general application throughout the country. It implies that all milk-producing herds shall be kept free from tuberculosis, and shall be periodically inspected by experts. Tuberculosis is so insidious and easily propagated, cleanliness is so difficult to maintain, and men capable of supervising dairy herds are so scarce that for years to come the ideal of a pure source over the whole country must remain an ideal. Nevertheless there is in existence an increasing number of producers of certified and Grade A tuberculin-tested milk, who show that it is practically possible to keep herds free from disease and to market milk —but at a price—safe for children without heat treatment.

The important question is what measures the legislature should adopt at the present time to reduce the incidence of milk-borne diseases, of which tuberculosis is by far the most formidable. Opinions are divided into two main schools. One concentrates on compulsory pasteurisation: the other regards pasteurisation as an unfortunately necessary makeshift, which, if made compulsory, would indefinitely postpone the attainment of the end which it thinks the only one worth aiming at—the universal production of clean raw milk. A group of representative medical men, headed by Lord DAWSON, have recorded their opinion [4] that, "while no effort should be relaxed to improve milk at the source, the entire milk-supply—excepting 'certified milk'—should be pasteurised." Prof. J. C. LEDINGHAM has roundly declared that [5] "no raw milk can be regarded as safe." The other side is represented by Col. C. MADDOCK, the honorary secretary of the organisation of the producers of tuberculin-tested milk; in a letter to this journal he states that,[6] "treated milk is not of equal value to fresh milk," that it is important to preserve "an open market for the sale of fresh milk from licensed tubercle-free herds at a reasonable price," and that to tamper with one of Nature's foods may be "putting the hands of the clock back." The advice which seems to us, however, to carry the greatest conviction and to suggest a positive course of action most suitable to the circumstances is that of Dr. W. G. SAVAGE, the county medical officer of health for Somerset, which is supported by the *Medical Officer*.[7] Dr. SAVAGE has studied the whole problem of milk production in a big milk-producing county and has made himself familiar with all its aspects; those of the farm and factory as well as those of the laboratory. In THE LANCET of March 7th,[8] after weighing the evidence, he suggested that an Act should be passed enabling the large local authorities, after inquiry by the Minister of Health, to require all milk produced or consumed in or entering their area, other than certified or Grade A (T.T.) milk, to be pasteurised. The advantages which such a scheme would possess include the effective control which it would give to progressive authorities; the experience of pasteurisation which would result from its operation; the mitigation of hardship to the small local dealer compared with that which would fall on him under an Act affecting the whole country; and the elimination of the present practice of inefficient heat treatment simply to keep milk from going bad before delivery. The powers given to a local authority would include powers to simplify and encourage the production of clean milk from tuberculosis-free cows—i.e., to adopt measures such as an agreed simplification of nomenclature, unification of control, and veterinary assistance. But whatever the immediate action advised, it is essential that all concerned should keep it in the front of their mind that the production of clean milk from healthy cows must be increased by every possible means. Some of these means are suggested by Dr. SAVAGE in his article. The suggestion has been made that the Government should set up a Royal Commission to inquire into the whole question of milk production. The matter is too urgent and important to be shelved in this way. There is at the present moment a committee of the People's League of Health in session on the problem of bovine tuberculosis; it includes among its members, besides Dr. SAVAGE, Col. MADDOCK, and Prof. LEDINGHAM, representatives of the largest producing firms and of the scientific aspects. Its report will be of great value, and until it is published there is no need for the duplication of the work through any other body.

TUBERCLE IN THE BLOOD.

THE game of cross questions and crooked answers has been thoroughly well played in the last 20 years on the subject of tubercle bacilli in the blood stream. The early experimenters, in endeavouring to find tubercle bacilli in centrifuged blood, fell into various pitfalls. Either acid-fast bacilli crept in from extraneous sources or artefacts were mistaken for tubercle bacilli, and positive results in some cases reached as high as 100 per cent. This line of action was therefore abandoned as unfruitful and workers next took to animal inoculation tests. Here again the results were wildly variable, some workers encountering dismal failure, others reporting a high percentage of positive results.[1] A new phase has now been reached by the invention of highly specialised culture media on which tubercle bacilli can be grown in primary culture with great readiness. Such media are those of Sweany and Evanoff [2] and Löwenstein. The medium devised by the latter, which introduces a new principle in bacterial culture, has yielded remarkable results, even to the extent of producing positive cultures in cutaneous lesions of suspected tuberculous origin. The next step would appear to be a careful study of the biological characters of the acid-fast bacilli grown on these new culture media. As a result of A. S. GRIFFITH's work on lupus strains it has long been known that the tubercle bacilli isolated from skin lesions may be of atypically low virulence for the guinea-pig. A strict comparison of the organism isolated from the blood of skin cases on Löwenstein's medium with the detailed work of Griffith is needed. There is, too, evidence in other directions that the acid-fast bacilli isolated on these special media from other sources are not always tubercle bacilli of typical biological characters. The whole question of these atypical strains—especially atypical in their effect on the guinea-pig, which is not exactly a living test-tube—is one of great interest and importance; but we shall be well advised to suspend judgment, at the moment, as to their precise clinical significance.

Turning now to the clinical side of the question there are still several points needing elucidation which when clear may explain the varying results of earlier workers. It is important to know, for instance, whether the positive findings are associated with what is generally known on the

Continent as Ranke's secondary stage and with that alone, or whether they are also indicative of a possible hæmatogenous spread in the tertiary stage in which dissemination has occurred, as it apparently does sometimes, even before (but generally after) resistance has broken down. To these questions must be added those pertaining to the numbers of tubercle bacilli circulating in peripheral blood, a problem which has recently been studied by Caussimon.[3] Obviously, as he points out, actual numbers have a bearing on the facility with which positive blood cultures can be obtained. A further question is raised in the experimental work of Prof. G. Dreyer and Dr. R. L. Vollum which appears on another page of this issue—namely, the life-cycle of the bacillus in relation to blood culture experiments. These writers have worked with a special technique[4] of growing *B. tuberculosis*, not on the surface of broth as is usually done, but by growth in the depths of veal-peptone-bouillon. In positive cultures small granules of growth appear at the bottom of the flasks on this media and can be transferred to other flasks. A series of subcultures of a special strain of *B. tuberculosis* was carried on in this way for three and a half years, and during that time the strain showed no tendency to produce a typical surface growth. Cultures thus grown occasionally turned out to be more virulent than cultures of the same strain grown on ordinary Petroff's medium. From this starting-point the authors proceeded to make a series of animal tests. Inoculating animals subcutaneously, intraperitoneally, or intravenously, they obtained positive cultures from the heart blood of these animals post mortem, and they believe that a bacillæmia is a regular occurrence in guinea-pigs infected with bacilli of human or bovine type, of high or low virulence. But this is not all. The writers noted that in granules from this type of cultures there were, in addition to the acid-fast rods, a considerable proportion of non-acid-fast organisms, some of which stained a deep blue with counter stain. They also noted numerous pairs of bacilli in a V or parallel arrangement in which one organism was more or less acid-fast while the other had taken up the counter stain. This arrangement was seen so regularly that the authors were driven to the conclusion that the non-acid-fast member had probably grown directly from the acid-fast one. They are therefore of opinion that these non-acid resistant organisms are of the greatest importance in the biology of the tubercle bacillus and suggested that such forms of the bacterial cell, whether growing in culture or in a tuberculous lesion, may be so small as to pass through a filter which would hold back most bacilli. They believe that as these smaller forms increase in size and age they acquire the property of fixing stain and eventually become acid-fast, and presumably are then too large to pass through the pores of the bacterial filter.

This work carries us back to the researches on the so-called filtrable virus form of the tubercle bacillus which has been so conspicuous a part of French investigation during the last few years. The whole question is fraught with very considerable technical difficulties which perhaps only the trained laboratory worker fully appreciates and much taking of pains will be necessary before a conclusion can be reached. As Prof. Dreyer and Dr. Vollum remark, the weight of evidence at present appears to be against the filtrability of the infecting material through the finer filters, such as Seitz and Chamberland L 5, but they give their support to the side of those who believe that "the acid-fast organism of Koch's classical description is not the only form in which *B. tuberculosis* occurs." This view of the matter has exercised the minds of bacteriologists for 30 years or more. Most of the previous work has been done with sputum, pus, and tuberculous tissue, and Dreyer and Vollum have added new interest to the problem by approaching it from a fresh angle—viz., blood culture in experimental animals. Their descriptions of the bacilli in deep cultures are not unlike those in very old cultures; vide for example a short account given some years ago by Gloyne[5] of a culture which had remained untouched for a period of nearly six years but was still viable. The appearances on the old culture, to which possibly Dreyer and Vollum's deep culture bears some analogy, doubtless exemplify an attempt of the bacillus to live in an unsuitable environment. How far the tubercle bacillus adopts this method of maintaining itself under unfavourable circumstances in the human body we do not know.

THE SURGEON'S RESPONSIBILITY.

Well might Lord Justice Scrutton observe that the recent appeal in Dunlop *v.* James was important to the medical profession. The Court of Appeal judgment (noticed in The Lancet a fortnight ago) seems to fix upon the operating surgeon the legal responsibility for checking the tally of swabs and to negative the delegation of this duty to a nurse, however perfectly trained. "It is said for the defendant," remarked the Lord Justice, "that the doctor is quite entitled to rely on the count of a competent person, although competent persons do make mistakes. Before there is any count, there is a duty on the doctor." Lord Justice Greer followed to the like effect. "The fact that counting may be exercised by some other person does not absolve the doctor from the necessity of making some reasonable search before he puts any question to the nurse with regard to the count." As will presently be seen, Dr. Dunlop made such a search, but nevertheless has to pay a substantial sum in damages and costs. Whether it be the fault of the law or the fault of the jury, this doctrine of the surgeon's responsibility seems to ignore the common and necessary practice of modern surgery, the interests of the patient and the specialised efficiency of the trained nurse.

The facts of Mrs. James's action against Dr.

[4] The Lancet, Jan. 3rd, p. 9.

[5] Gloyne, S. R.: Tubercle, 1920, ii., 12.

Dunlop are briefly these. Dr. John Dunlop, assisted by Dr. James Sullivan, performed a gall-bladder operation upon her husband at the Ebbw Vale Hospital in December, 1928. There were also present Dr. John Sullivan, the anæsthetist, Miss Ford, the matron (who had charge of the instruments), and Miss Hutchings, the theatre sister, besides two probationers. The patient required oxygen, and it was twice necessary to use artificial respiration; otherwise the removal of a large number of gall-stones proceeded normally, the operation appeared successful, and Mr. James was in due course sent home. His health, however, did not mend. In the following March a further examination at the Llanidloes War Memorial Hospital showed that a swab had been left in his body, and soon afterwards the patient died. His widow sued Dr. DUNLOP at Shropshire Assizes. There was evidence that at the original operation the question was asked, "Are all swabs out?" and that the answer was "Yes." Mr. Justice BRANSON pointed out to the jury that there was also evidence that both Dr. Dunlop and his assistant had made some independent search; they had "felt round" to see if any swabs were left and had found none. In his answers to interrogatories, earlier in the action, Dr. Dunlop had replied in the negative to various questions whether he had, during or after the operation, counted the swabs used or removed from the body or whether he had taken any steps to check the numbers. Clearly he relied on the ordinary surgical practice by which this task is left to a trained sister. The evidence of what occurred at the operation was hardly in dispute, but the statements as to the checking by the sister were not so definite as they should have been, though, of course, the witnesses were speaking of something which happened some time ago. Neither plaintiff nor defendant called Miss Hutchings (whose duty it was to keep tally of the swabs) as a witness. There was no doubt that Dr. James Sullivan asked the question, "Are all swabs out?" Four witnesses said they heard it. But the evidence as to the answer, which we may naturally assume must have been in the affirmative, was varied. Dr. Dunlop said he heard a reply in a woman's voice, coming from where the matron and theatre sister was standing; he did not remember the exact words, but the answer was satisfactory. Dr. James Sullivan said very definitely that he heard the reply "Yes" from Miss Hutchings, to whom his question was addressed. Dr. John Sullivan said he heard a woman's voice say "Yes," and was convinced it was Miss Hutchings. It is true that Miss Ford, the matron, could not say she heard any reply; but it may fairly be stated that there was reasonably sufficient evidence that the theatre sister gave the assurance which had been asked for. The significance of these details of the evidence will appear when we come to the material questions put by Mr. Justice Branson to the jury. The first question was: Did the defendant make such personal search in the wound as was reasonable and proper, having regard to all the circumstances of the case? The jury answered "No." Secondly, did the defendant receive an assurance from Miss Hutchings that all the swabs were removed? The jury answered, "Evidence not satisfactory." Thirdly, having regard to all the circumstances of the case, was the defendant justified in closing the wound without making more extensive search for swabs, either by reason of such search as was made or by reason of the assurance of Miss Hutchings or by a combination of the two things? The jury answered "No." These answers amounted to a verdict of negligence against Dr. Dunlop, and damages of over £2000 were awarded. It may be added that on another and different allegation of negligence Dr. Dunlop succeeded; an attempt to fix him with blame for not having used tagged or taped swabs failed, medical experts on both sides agreeing that such use was neither universal nor indispensable.

Dr. Dunlop appealed, on the ground that the jury's verdict was against the weight of evidence, and asked for a new trial. But the Court of Appeal has refused to say that the jury gave a perverse verdict. Lord Justice Scrutton seems to have thought they might naturally be impressed by the "size of the towelling," and might well feel it was careless not to have removed something so large, though indeed it had been amply explained by various witnesses that the movement and discoloration may make the detection of swabs by no means a simple and automatic process. As to the jury's answer that the evidence of the nurse's assurance was "not satisfactory," this might mean, said the Lord Justice, that the jury attached importance (as they were entitled to do) to the three facts that the defendant did not call Miss Hutchings as a witness, that the matron was not able to say she heard the reply, and that Dr. Dunlop's testimony here might suggest that he assumed the particular happening of what usually happened. If the jury's answer to the second question stood ("evidence not satisfactory"), it was an end of the case. Dr. Dunlop, of course, could not defend himself by relying on the responsible nurse's assurance that all swabs were out if the jury was not satisfied that the assurance had been given. In view of the evidence already summarised, one would imagine that most juries would have been reasonably satisfied on the point. The judges of the Court of Appeal do not say that they would not themselves have been satisfied. They merely say that, if the jury was not satisfied, there was some ground for a jury to take that view, and therefore the verdict cannot be disturbed. Unfortunately, the answer "evidence not satisfactory" makes the case an indifferent opportunity for a further appeal to the House of Lords upon the broad issue which so vitally affects all surgeons.
